- critical thinking and reasoning (searching for relevant information, selecting relevant information, being systematic and logical, weighing evidence, identifying errors, constructing defensible arguments, making informed decisions)
- constructive and systematic inquiry and knowledge creation (posing questions, seeking answers, planning, investigating, producing, applying and extending)

- information management and retrieval (searching, selecting, evaluating, organizing, drawing conclusions and communicating findings)
- communication skills (oral, written and multimedia).

Metacognitive competencies

Metacognition is thinking about thinking, especially managing one's own learning, sometimes identified as a fourth facet of knowledge (Krathwohl, 2002). Metacognitive competencies typically include:

- self-reflection, self-evaluation and self-adjustment
- self-regulation, self-management and self-direction
- self-awareness and self-efficacy
- capabilities for life-long-learning (learning-to-learn).

Personal (or intrapersonal) competencies

These are usually considered as attributes, dispositions or propensities, including:

- adaptability and flexibility
- creative endeavor, enterprise, initiative and entrepreneurship
- curiosity and imagination resilience and persistence
- civic mindedness.

Whether, or to what extent, these can be taught is unclear (Bereiter and Scardamalia, 2012), and this has implications for their assessment.

Interpersonal competencies

These are based on a recognized need in the modern world for empathy and respect in accommodating different opinions, lifestyles and cultures, which can also be beneficial in solving problems. They include:

- collaboration and teamwork
- social, cultural and intercultural awareness
- leadership, interpersonal support and conflict management.

International commitments to 21st century competencies

There is widespread "in principle" commitment around the world for students to develop these kinds of competencies (Australian Curriculum, Assessment and Reporting Authority, n.d., 2019; Ananiadou and Claro, 2009; Care et al., 2016a, 2018; Cheng, 2017; Cook and Weaving, 2012; European Commission, 2020; Gordon et al., 2009; Russell, 2016; Taylor et al., 2020; and UNESCO, 2019). For example, in a scan of 102 countries, Care et al. (2016) concluded that most countries "acknowledge the importance of breadth of skills somewhere in their public documents, and many list a number of specific skills or competencies that the education system intends to provide" (p. 4). Even so, "few countries show evidence that these skills are consistently identified in national documents, including mission and vision statements, curriculum frameworks, and descriptions of how skills progress for learners" (p. 4). Commitment has been largely verbal rather than practical.

Declarations of intent are clearly insufficient to create system-wide change in educational practice. Important requirements for change include system-wide commitment, development of resources and professional development. Even more critical is producing operational definitions of the competencies and developing sound principles and procedures for their assessment. These are matters on which a start has been made but progress has been slow (Care, 2018; Care et al., 2019; Russell, 2016; Saavedra and Opfer, 2012).

Progress in assessing 21st century competencies

Commitment to 21st century competencies around the world can be summarized as an emphasis on

substantive knowledge in (at least) a curriculum core; knowledge having structure, complexity and transferability; cognitive strategies covering a range of thinking, enquiry and communication skills; metacognitive strategies relating to self-direction, monitoring and regulation; personal attributes such as adaptability, creativity, curiosity and persistence; and interpersonal skills such as collaboration and cultural awareness.

Maxwell (2021, p. 97).

While these competencies are not newly discovered (Kereluik et al., 2013), what is different is their importance and applicability from an educated elite to everyone (Kay, 2010; Pellegrino and Hilton, 2012). They have also acquired new contextual characteristics and changes in their relative importance. For example, “problem solving” now requires accessing, managing, integrating and evaluating large amounts of “disorderly” information, while “interpersonal skills” such as collaboration now become more salient than previously (Dede, 2010).

It is sometimes suggested that specific competencies may be assessable using current assessment approaches; for example, the Program for International Student Assessment [PISA] includes complex assessment of critical thinking (OECD, 2018). However, this may misrepresent the transformative implications of the competencies (Care, 2018; Care and Luo, 2016; Cook and Weaving, 2012; Pepper, 2011; Silva, 2008). Voogt and Roblin (2012) suggest that: “current assessment models, which mostly focus on the measurement of discrete “bits” of knowledge, fail to assess 21st century competences and call for assessment grounded in authentic and complex tasks” (p. 312). The need for “real world” or “authentic” assessment contexts is a common concern (Care and Kim, 2018; Care et al., 2018; Lai and Viering, 2012).

The use of complex assessment tasks also recognizes the practical impossibility of assessing all of the competency categories and sub-categories separately. Rather, assessment needs to focus on constellations of competencies operating synergistically. Examples include literacy tasks in combination with critical thinking and self-management skills, problem-solving tasks that involve communication and collaboration, portfolios (as collections of student work), presentations and constructive activities, and problems involving computer simulations of real-world scenarios (Care et al., 2016; Koenig, 2011; Microsoft Partners in Learning, 2012; Soland et al., 2013).

A further complication is whether competencies are embedded within domains of learning or can be cross-curriculum (transversal). The latter assumes generalization of the competency beyond the confines of particular subject matter, that is, that the competency is generic, and can transfer to contexts beyond those in which it is initially acquired. This remains a contentious issue (Shepard, 2019).

While progress has been slow and piecemeal, developments in assessing 21st century competencies can be identified for each of the domains. The following discussion identifies several key developments around the world.

Assessing ICT-related competencies

Siddiq et al. (2016) conducted a substantial international review of existing ICT literacy assessments. They found substantial convergence in emphasis but considerable ambiguity in definitions of ICT literacy (otherwise referred to as digital literacy). They chose a well-researched and comprehensive framework, DIGCOMP (Ferrari, 2013), as the basis for their review, with modifications. The revised framework consisted of six competence areas (here paraphrased): browsing, searching, filtering, evaluating, storing and retrieving information; communication involving interacting, sharing, engaging and collaborating through digital technologies; digital content creation; problem solving through innovation and collaboration; technical and operational skills; and safety management and ethics. A total of 38 tests from 17 countries was analyzed. They note that Australia was the only country to systematically embed ICT literacy in the curriculum and assess it at a national level, in this case, through sampling testing every third year at two grade levels (6 and 10); the Australian national curriculum includes ICT Literacy as one of several general capabilities (ACARA, n.d) with relevant content descriptions and elaborations in each learning area of the curriculum, and rubrics detailing several elements and sub-elements across a learning continuum of six levels [<https://www.australiancurriculum.edu.au/media/1074/general-capabilities-information-and-communication-ict-capability-learning-continuum.pdf>]

In their findings, Siddiq et al. (2016) conclude that the complexity of the ICT literacy concept is not yet matched by commensurate complexity in its assessment, indicating “a gap between how ICT literacy is theorized in research and dominant frameworks, and how the concept is operationalized in curriculum and assessment” (p. 77). They report a majority focus on handling digital information, with some attention to digital content creation, communication and technical/operational skills, but little attention to other aspects of ICT Literacy, such as “problem solving with ICT, digital communication, and online collaboration” (p. 78). They also found a preponderance of traditional testing, with limited use of authentic tasks, such as would be relevant, for example, for assessing collaborative problem solving.

One framework, taking up the authentic assessment challenge, charted ICT literacy across four strands for Computer and Information Literacy (CIL)—understanding computer use; gathering information; producing information; and digital information—and two strands for Computational Thinking (CT)—conceptualizing problems; and operationalizing solutions. Other developments are reported by Ainley et al. (2016), Fraillon et al. (2019), Kaarakainen et al. (2018), Siddiq et al. (2017), van Deursen et al. (2016) and Wilson et al. (2015, 2018a,b).

It can be noted that ICT-related competencies include other competencies, such as cognitive (e.g., problem solving) and interpersonal (e.g., collaboration) competencies, in the context of ICT. This highlights the interrelationships among various 21st century competencies, and the possibilities for combining two or more different competencies (from the different categories listed earlier) in a single assessment. ICT-related competencies are typically represented as cross-curriculum (generic or transversal) competencies, but they may be learned through application within specific domains of knowledge.

Assessing conceptual knowledge competencies

Conceptual knowledge is located within domains of knowledge because it represents desirable cognitive dimensions of the subject matter. To become expert in a domain of knowledge is to develop conceptual depth and complexity, going beyond factual knowledge to include knowledge structures and their application in solving authentic problems. Factual knowledge is “surface learning”, which can be usefully assessed as foundational for deeper learning, but is inadequate as the ultimate aim of domain learning (Hattie, 2009).

Assessment of domain knowledge therefore needs to go beyond assessment of routine memorization. Binkley et al. (2012) say:

The crux of twenty-first century skills is the need to integrate, synthesize, and creatively apply content knowledge in novel situations. Consequently, twenty-first century assessments must systematically ask students to apply content knowledge to critical thinking, problem solving, and analytical tasks throughout their education, so that we can help them hone this ability and come to understand that successful learning is as much about the process as it is about facts and figures (p. 25).

Consequently, assessment needs to extend beyond factual recall and simple understanding to reveal deeper conceptual understanding and knowledge structures, something that typical standardized tests cannot do (Sawyer, 2006). Assessments that can assess such competencies are well known but require further development. They include performance assessments, projects, presentations and portfolios, focusing on the deep structure of the knowledge domain and its application in authentic situations (Maxwell, 2021). The recommendations of Lai and Viering (2012) still hold true, especially the need for: open-ended and ill-structured tasks; meaningful, authentic or real-world tasks; making student thinking and reasoning visible; and innovative use of technology. Interesting examples can be found in curriculum materials around the world, for example, *Australian Curriculum Sample Assessments and Senior Assessment Hub* [Queensland Curriculum and Assessment Authority: <https://www.qcaa.qld.edu.au>], *New Zealand Assessment Resource Banks* [New Zealand Council for Educational research: <http://arbs.nzcer.org.nz>].

Cognitive competencies

Cognitive competencies are about thinking, reasoning, inquiry and problem solving. The extent to which these competencies can be learned and assessed generically, that is, applicable in any context, is contentious. Typically, in education systems, these competencies are embedded as learning aims and assessable components of subject domains (Leutner et al., 2017). Clearly, problem solving in different domains, for example, history versus science, has different characteristics, and capability in one domain may not transfer to another domain. A knowledge base is essential for the thinking. For assessment of generic competencies, the relevant knowledge base can be provided as part of the task specifications, but competence may not then transfer to more realistic situations (Ercikan and Oliveri, 2016).

The “complex problem solving” component of cognitive competencies has been given substantial attention and exploration in recent years (Krkvic et al., 2018). Yet, Funke et al. (2018) conclude that its definition and assessment remain inadequate and require more research. One approach that has shown some promise for large-scale testing is reported by Herde et al. (2016). Their approach involves computer-based tasks that set a problem stemming from provided information. They illustrate their explanation with a task, *Climate Control*, from PISA 2012 (OECD, 2013a). The approach allows assessment of both knowledge acquisition and knowledge application as two fundamental stages of problem solving. A potential advantage of computer-based tasks is that the information available from the computer log-files can provide insights into the strategies that students used in solving the problem, something about which little is currently known.

A different approach was taken by Griffin and Care (2015), focusing on collaborative problem solving (combining interpersonal and cognitive components) and using ICT as a tool for group collaboration rather than as a tool for solving the problem (see also Care et al., 2016b). Examples of such tasks were developed, and scored in terms of various cognitive and collaborative skills. Some success was experienced in implementing the assessments across the six countries involved in the research.

Metacognitive competencies

The long history of research on metacognition (Azevedo, 2020; Lai, 2011) has not led to its systematic assessment in educational practice. Assessment of metacognitive competency typically relies on self-report to reveal the thinking processes, thinking strategies, self-awareness, self-monitoring and self-perceptions of the student. This can involve questionnaires, observation schedules and interview protocols (Karlen, 2016; Kuzle, 2018; Marulis et al., 2016; Roebers et al., 2020; Ozturk, 2017; Rovers et al., 2019; Tuck and Moxley, 2017). One useful strategy is asking students to “think aloud” during or after completing an assessment task to reveal the strategies used (Bannert and Mengelkamp, 2007; Desoete, 2008). Such approaches are more useable in classroom contexts than large-scale testing. Their veridicality is often doubtful. It could be argued that successful metacognitive strategies should be implicit in the successful completion of tasks that require the use of such strategies. Assessment of metacognitive competence is therefore more important as formative assessment than as summative assessment.

A substantial analysis reported by Caena (2019) combines metacognitive with personal and interpersonal competencies. This combination is expressed as the Personal, Social and Learning-to-Learn Competency (LifeComp), one of eight competencies

adopted by the European Union (European Commission, 2018; European Union, 2019). A framework was proposed consisting of “cross-cutting core elements (self-regulation, growth mindset, empathy), which support compound competences for personal development (adaptability and wellbeing), social development (communication and collaboration), and learning to learn (critical thinking and managing learning)” (Caena, 2019, p. 32). This framework provides a useful foundation for further development of assessment processes.

Personal (or intrapersonal) competencies

Calls for the development of personal competencies (Herman and Hilton, 2017; Pelligrino and Hilton, 2012) have not seen much progress. Duckworth and Yeager (2015) analyze the inadequacies of typical assessments of personal competencies, such as self-report surveys, teacher/parent-report surveys, and teacher observations for program evaluation, school accountability and individual diagnosis. Surveys suffer from reference bias, social desirability bias, acquiescence bias, and faking; observations reference exhibited behaviors rather than the targeted internal emotions and thoughts, and these behaviours may not generalize to other tasks and other contexts. Nevertheless, development of a suite of assessment approaches for use in the classroom would assist teachers in focusing on the development of these competencies.

One such approach, the Mission Skills Assessment, was developed for the Independent Schools Exchange (INDEX) by Educational Testing Service (ETS) (Petway et al., 2016). This was a web-based assessment of six constructs, covering personal and interpersonal competencies: creativity; curiosity; ethics; resilience; teamwork; and time management. Despite the admitted inadequacies, six Likert-item scales were constructed for use in self-report and teacher-report surveys. Soland et al. (2013) report the usefulness of this approach for drawing attention to these competencies and creating conversations in classrooms about them, but there does not seem to have been further development of these scales. An alternative that has received some attention is Situational Judgment Tests (Herde et al., 2019).

A distinction can be made between a skill and a quality, for example, critical thinking versus critical thinker (Bereiter and Scardamalia, 2012). Critical thinking involves logical evaluation of arguments; becoming a critical thinker requires a deeper level of commitment and engagement. In other words, critical thinking is a cognitive competency while being a critical thinker is a personal quality. Critical thinking capability might be assessed by a test consisting of multiple-choice items, but whether a person is developing into a critical thinker requires judgment by an observer over time.

Creativity is a related personal quality. Lucas (2016) reports a promising model of creativity in terms of five habits of mind: inquisitive; imaginative; persistent; collaborative; and disciplined. Assessment trials of the inquisitive dimension were reported, assessing students on strength, breadth and depth along a four-step progression from “awakening” to “adept”. This is a promising set of ideas, further developed in Lucas and Venckutė (2020) and Venckutė et al. (2020), who review international approaches to teaching and assessing creativity.

Other developments are difficult to find. Bolden et al. (2020) surveyed developments in assessing creativity, focusing on its formative development, and reveal some of the complexities and confusions about creativity and its assessment, pointing to the need for greater construct consistency and clarity. They conclude that “assessment strategies that include (a) explicitly establishing and defining criteria for creativity and creative processes, behaviors, and products; and (b) engaging students in supported and particularly teacher-supported self-assessment emerged as positive supports for creativity in classrooms” (p. 369).

Interpersonal competencies

The Rand Education Assessment Finder (<https://www.rand.org/education-and-labor/projects/assessments.html>) is a web-based repository of assessments of interpersonal, (intra)personal and cognitive competencies. Its construction is described in Schweig et al. (2018). This shows that a large number of such assessments exist, evidencing a variety of different constructs of relative quality and value.

There is a long history of interest in social and emotional learning, as a combination of interpersonal and (intra)personal competencies (Jones et al., 2019). Berg et al. (2017) found substantial diversity in how these competencies are represented and defined. In order to impose some coherence, their study used a classification of competencies organized into six domains: cognitive regulation (e.g., attention control, critical thinking); emotional processes; interpersonal processes; values (e.g., civic, ethical); personal perspectives (e.g., optimism, openness); and self-identify (e.g., efficacy, esteem) with explanations of each (p. 43). Their review classified a range of existing measures in terms of their characteristics. However, the appropriateness and usability of different measures for different contexts needs to be considered.

At an international level, OECD has committed to conducting a regular survey of social and emotional skills (defined as how people manage their emotions, perceive themselves and engage with others) targeting 10 and 15 year olds and using 5-point Likert items. The assessment covers 17 skills across five domains: task performance; emotional regulation, collaboration; open-mindedness; and engaging with others (<https://www.oecd.org/education/ceri/social-emotional-skills-study/>). The first cycle of assessment (2018–20) has been reported (OECD, n.d), including a discussion of the development of self-efficacy, metacognition and critical thinking, and their interrelationships.

Another dimension of interpersonal competency receiving substantial attention is collaboration. Child and Shaw (2016) provide an overview of assessment of collaboration, defined in terms of six facets: social interdependence; introduction of new ideas; cooperation; conflict resolution; sharing of resources; and communication. They make an important distinction between

the collaborative process (the quality of the team activity) and the collaborative outcome (the quality of the knowledge and understanding produced for solution of the problem).

Collaboration is typically, almost inevitably, linked with problem solving. [Care et al. \(2016\)](#) elaborate both strands in collaborative problem solving, with collaboration consisting of three social components—participation, perspective taking and social regulation—and problem solving consisting of two cognitive processes—task regulation and knowledge building. Contributing sub-skills for each of these five components enable design of assessment tasks and mapping the progression from lower to higher competency. Construction and implementation of an online task requiring collaborative problem solving between two students is described. The authors emphasize the inadequacy of traditional methods of assessment for such competencies and the need for “innovative and advanced” approaches of assessment if they are to become part of the expected learning outcomes in education systems.

Implications for future assessment practice

The implications of a commitment to 21st century competencies extend not just to developing new assessments for those competencies but to reframing the way in which assessment is designed and implemented in schools. For example, assessment needs to incorporate application of knowledge and processes in different contexts, access to and use of information resources, and collaborative as well as individual problem solving ([Wilson et al., 2015](#)). This requires assessments that are situated in authentic real-life contexts, assessments requiring multiple steps and a chain of reasoning, assessments that incorporate several competencies, and assessments with open response formats ([Care and Kim, 2018](#); [Cook and Weaving, 2012](#); [Voogt and Roblin, 2012](#)). Progress in the development of such assessments has been slow and uncoordinated. Most assessments in use around the world remain traditional and narrow, limited to simple recall and routine tasks, with limited attention to most of the typically endorsed 21st century competencies ([Darling-Hammond, 2017](#)). While the complexities are substantial, examples of innovative approaches are beginning to emerge (for example, [Care et al., 2018](#)).

There remains a problem of definition of various competencies—giving a clear and precise account of the relevant construct and the learning goals indicative of each competency ([Care and Luo, 2016](#); [Care et al., 2019](#); [Lucas, 2021](#)). Preferably, too, levels of progression or stages of development are needed to represent increasing complexity in the construct, indicating greater depth of learning rather than greater quantity ([Bereiter and Scardamalia, 2012](#); [Forster and Masters, 2010](#); [Lucas, 2016](#); [Jin et al., 2019](#); [Shepard, 2018](#)).

Once the constituent components have been determined, assessment tasks can be constructed. Given the synergistic nature of competencies, such assessment tasks need to cover constellations of competencies ([Care et al., 2016](#)). However, task development may not be the greatest challenge. [Care et al. \(2020\)](#), working with teams from Cambodia, Mongolia and Nepal on assessment of problem solving, critical thinking and collaboration, found that the bigger problem was the adaptation needed in teaching practice and classroom culture. Both philosophical and logistic issues were involved. Commitment to change required teachers being convinced it was worthwhile. It was concluded that an evolutionary approach, based on building teacher capacity and confidence, has most chance of success.

The prospect of this happening quickly appears slim. For political and cultural reasons, national education systems are firmly wedded to existing practices and are difficult to change. As [Issacs and Gorgen \(2018\)](#) note:

Educational cultures differ across jurisdictions, permeating their assessment structures and processes in idiosyncratic ways. Different cultures and contexts give rise to a variety of accepted practices in national assessment and examination systems across the world and often act as impediments to change (p. 308).

Emancipation from existing practices therefore requires different strategies in different countries, for example breaking the monopoly of standardized testing in the US versus breaking the monopoly of public examinations in many other countries. Comprehensive calls for change in the US, such as the “next generation assessment” proposals of [Darling-Hammond \(2014\)](#) and [Conley \(2018\)](#), have seen some take-up and some backsliding. In other parts of the world, the need for change in public examination systems is recognized but requires careful management of potential political and practical repercussions ([Baird et al., 2018](#); [Kellaghan and Greaney, 2020](#)). A standout case is Queensland Australia where all high-school graduation assessment was school-based for fifty years, allowing for the development of broader and deeper assessment ([Cumming, 2020](#); [Maxwell and Cumming, 2011](#)), but which has succumbed recently to pressures for national conformity and the reintroduction of public examinations ([Campbell, 2018](#)). As well, Australian national testing of literacy and numeracy in Years 3, 5, 7 and 9 has had typical narrowing effects on the curriculum through earlier years ([Cumming et al., 2019](#)).

Establishing a link between national aspirations for broader learning, as expressed in 21st century competencies, and assessments at all levels of an educational system needs an holistic approach in which “various components of assessment and evaluation should form a coherent whole ... generate synergies between components, avoid duplication and prevent inconsistency of objectives” ([OECD, 2013b](#), p. 2). Ensuring that all relevant learning aims are given attention at appropriate levels within an educational system requires a systems approach. In a systems approach, assessment is planned as a whole, ensuring appropriate coverage and

balance across all components of the education system (state/district, school and classroom; year levels; subjects or areas of study). This allows the overall system to be coherent (so that different components are part of an overall plan), comprehensive (so that the components contribute toward coverage of all relevant learning outcomes), and continuous (so that there is systematic developmental progression from earlier assessments to later assessments) (Maxwell, 2021). This also establishes a link and complementarity between accountability assessment and classroom assessment.

Judging progress in learning on only some of the learning aims that are considered important, whether the unit of analysis is the nation/state, district, school, classroom or student, provides incomplete and distorted information. What is needed is a profile approach to monitoring and reporting progress, where the different learning outcomes are considered as separate dimensions, and all aspects of learning are recognized and valued. Further discussion of these issues is found in chapters 3 and 5 of Maxwell (2021).

Introduction

International large-scale assessments (ILSAs) have become key sources of information for educational research and policymaking. As they provide information about relevant educational indicators, such as students' achievement in core domains, teachers' job satisfaction, or employees' skills to solve problems with technology, both nationally and internationally, ILSAs are pieces in the "puzzle" of accountability. Accountability in education has many facets, focusing on the processes of performance reporting as well as the technical, political, and institutional processes (Levin, 1974). It broadly refers to "a process which involves the duty both of individuals and the organizations of which they are part to render periodically accounts for tasks performed"

(Neave, 1987, p. 70). The following sections are based on this broad definition and focuses on the performance reporting and the information ILSAs can provide about the possible processes leading up to it.

This chapter discusses future directions of ILSAs in the context of accountability and describes their current status. To achieve this, we specifically aim to:

- Provide **background knowledge** of ILSAs through describing and discussing their characteristics, developments, and purposes;
- Provide brief overviews of the **current ILSA domains, populations, and contextual information** and to discuss the **future directions and needs** within these areas;
- Describe and illustrate the **potential and innovative approaches of ILSAs** with regards to the types of data, data sources, and methodological advances.

Context, history, and purposes of ILSAs

As we review the current status and future directions of international large-scale assessments in the context of accountability, we refer to their key characteristics and outline their innovations in light of their historical developments and contexts. To provide readers with some background knowledge of these issues, we (a) define and characterize ILSAs; (b) sketch four main eras of their development; and (c) describe their main purposes.

Definition and characteristics of ILSAs

The common definition of ILSAs is much broader today than it had been when ILSAs started (see **Definition and characteristics of ILSAs** section). The early ILSAs targeted representative samples of student populations across countries and mainly assessed their mathematics and science competence.

The definition of ILSAs lies in the very name which refers to assessment studies that are **international** and include **large-scale samples**. Yet, today many would include both assessment studies as well as surveys when referring to ILSAs. For instance, TIMSS is an **assessment study** capturing student competence in science and mathematics (Mullis and Martin, 2017), while TALIS is a **survey** of teachers capturing aspects of the teaching profession and teacher education (OECD, 2019b). Moreover, international and regional studies are often referred to as ILSAs (IEA, 2017). Furthermore, ILSAs may target students in school or samples outside of school, such as adults or children in pre-primary education. ILSAs may assess core subject domains, such as mathematics and reading, or cross-curricular domains, such as problem solving, digital literacy, and global competence. Nowadays, ILSAs would refer to studies that are meant for accountability informing educational policy at the national level rather than studies designed solely for research purposes (Addey et al., 2017).

ILSAs have developed extensively since the first IEA studies. One driver of this development has been the implicit alignment of ILSAs with the comprehensive model of educational outcomes—a model emphasizing all aspects of a dynamically changing school system at the system, school, class, and student level and their interactions (Stancel-Piątak and Schwippert, 2022; Blömeke et al., 2022; Wagemaker, 2020; Creemers and Kyriakides, 2008). Another driver was to accommodate the needs of societies, educational research, policymaking, and accountability systems (Addey et al., 2017). This development motivated the inclusion of new types of educational outcomes, new populations, and countries. Regional studies, such as Southern and Eastern Africa Consortium for Monitoring Educational Quality (SACMEQ) are examples of new ILSAs that were established to better adjust for the local context. PIAAC is an example of an ILSA targeting an adult population rather than students, and OECD International Early Learning and Child Well-being Study (IELS) is an example of an ILSA that samples children in pre-primary education. Examples of ILSAs that include new types of outcomes other than achievement in mathematics, reading, and science, are ICILS that assesses students' digital skills, and PISA that started to include financial literacy in 2012 (Fraillon et al., 2020; OECD, 2020b). **Table 1** lists examples of ongoing ILSAs (for a complete list, please see <https://ilsa-gateway.org/studies/factsheets>).

Historical perspectives

There are a number of publications describing in great detail the history and development of ILSAs (see e.g., Wagemaker, 2020; Rutkowski et al., 2013; von Davier et al., 2012; Nilsen et al., 2022). The present chapter, however, provides only a brief overview.

The history of ILSAs can be considered in three main eras. In the **first era**, from the 1950s to 1995, ILSAs consisted of the early IEA studies, such as the *First International Mathematics Study* (FIMS) and the *Second International Mathematics and Science Studies* SIMS and SISS (Wagemaker, 2014). Research, rather than accountability, was the main purpose of these studies, and these studies focused on the opportunities to learn (OTL) and classroom characteristics, contributing to the research fields of curricular studies, OTL and teachers' competence and instruction (Scheerens, 2016). These ILSAs included representative samples of students from a narrow selection of developed, Western countries and assessed students' competence in mathematics and science in different cohorts (Medrich and Griffith, 1992).

The **second era** consisted of the ILSAs as we know them today and started with TIMSS in 1995 (Beaton, 1996). This era introduced ILSAs as steered by policy, and the results from PISA 2000 that triggered a shock for many countries, the so-called

Table 1 Examples of ILSAs, their main focus, and governing organizations.

<i>ILSA</i>	<i>Main focus</i>	<i>Organization</i>
ICCS (International Civic and Citizenship Education Study)	Students' knowledge, understanding, beliefs, attitudes, and behaviors with respect to civics and citizenship	IEA
ICILS (International Computer and Information Literacy Study)	Students' knowledge, skills, and understanding for successfully dealing with (dynamic) information and computer technology	IEA
PIAAC (Programme for the International Assessment of Adult Competencies)	Adults' proficiency in crucial information-processing skills, including numeracy, literacy, and problem-solving in technology-rich environments, and skills at home, at work, and in their communities	OECD
PIRLS (Progress in International Reading Literacy Study)	Students' reading performance at grade 4 in relation to their reading education, monitoring transitions from "learning to read" to "reading to learn"	IEA
PISA (Programme for International Student Assessment)	Students' ability to use their reading, mathematics and science knowledge and skills to meet real-life challenges	OECD
TALIS (Teaching and Learning International Survey)	Teachers' working life in school and principals' experiences with school policy, resources, professional development and training	OECD
TIMSS (Trends in International Mathematics and Science Study)	Students' performance in mathematics and science at grades 4 and 8, monitoring achievement trends and possible changes in education	IEA

"PISA-shock." This era reflects a shift for the ILSAs, from a focus on research to emphasis on accountability, from being dominated by researchers to being influenced by policy, and from receiving little attention by others than researchers to massive media attention (Addey et al., 2017).

The **third and present era** is characterized by recent developments of old ILSAs and the addition of new ILSAs. The number of ILSAs has increased, and new populations and types of outcomes were included (von Davier et al., 2012). The community working with the ILSAs and using the data increased immensely, and methodological competence capacity was built along with the increasing complexity of the data (Blömeke et al., 2022). This era is also characterized by a rapid development within information and communication technology and ILSAs' adopting of new assessment modes, such as adaptive testing. The massive attention from the media that started in the second era continued, but ILSAs received more critique from researchers and practitioners about the heavy influence of policy on education and the emphasis on testing, among other things (Addey et al., 2017).

Main purposes of ILSAs

Today, the main purpose of ILSAs is embedded deep in accountability, meaning that ILSAs provide knowledge to countries' authorities, informing evidence-based decisions. However, as Braun and Singer (2019) have noted, the purposes of ILSAs are diverse and vary in their appropriateness. Specifically, while ILSAs can deliver on comparative descriptions of educational outcomes, conditions, and inputs, drawing causal inferences on the basis of ILSA data is the least appropriate purpose. Indeed, the limitations of the sampling and study designs mainly allow for correlational inferences (Rutkowski and Delandshere, 2016). These correlations are, however, too often interpreted as causal effects (Gustafsson and Nilsen, 2022). The main threats to correlational inferences are omitted variables, confounding variables, reversed causality and, in the case of ILSAs, self-reports (Gustafsson, 2013). Specifically, reversed causality entails that one would not know whether the predictor (e.g., student motivation) affects the outcome (e.g., student achievement) or the other way around. Furthermore, omitted and confounding variables entail that one would not know whether it is the predictor (e.g., class size) that affects the outcome (e.g., student achievement) or whether there is an omitted variable (e.g., socio-economic status, SES) that actually predicts the outcome. Omitted variables can affect both the outcome and the predictor (Gustafsson, 2013).

To what extent ILSAs fulfill the purpose of providing knowledge for evidence-based decisions is a complex question and depends on the type of knowledge in question, on the type of ILSAs one refers to, and what characterizes the purposes of these studies. In the following, we will provide a brief overview of the purposes and characteristics of two of the most influential ILSAs, namely TIMSS and PISA.

PISA aims to measure the reading, mathematical, and scientific literacy students need in the future, while TIMSS aims to measure students' competence in mathematics and science corresponding to the countries' curricula (OECD, 2019a; Mullis and Martin, 2017). To this end, it means that PISA has a future perspective, focusing on what student should learn to manage their lives in future societies, while TIMSS has a retrospective perspective, measuring what students should have learned following their curricula (Blömeke et al., 2022). PISA includes cross-disciplinary domains (e.g., global competence; see also the chapter by Ozga, 2022; in this encyclopedia) and provides advice to countries' policymakers (Addey et al., 2017). TIMSS, on the other hand, provides

descriptive statistics rather than correlational analyses, and does not provide advice to countries' policymakers directly (Wagemaker, 2014).

PISA takes a top-down approach, where decisions are made by expert groups and policy makers (Blömeke et al., 2022). The OECD countries are in the main focus, although more developing countries are gradually joining the study. TIMSS takes a more bottom-up approach based on the collaborative enterprise by the participating countries (Mullis et al., 2020). While TIMSS is, to a large extent, motivated by research rather than policy, there is an increasing influence from policymakers (Blömeke et al., 2022). Compared to PISA, TIMSS has included more developing countries, although both studies have an increasing, heterogeneous mix of countries (Rutkowski and Rutkowski, 2018; see also the chapter by Rutkowski and Rutkowski, 2022, in this encyclopedia).

TIMSS measures "educational achievement in mathematics and science at the fourth and eighth grades, and sometimes the final year of secondary school" (IEA, 2021). The stated goal of PISA is to assess "the extent to which 15-year-old students near the end of their compulsory education have acquired the knowledge and skills that are essential for full participation in modern societies" (OECD, 2019a). While the goals of TIMSS and PISA are quite different, the goal perceived by policymakers is one and the same—accountability.

Future directions of ILSAs

In this section, we first provide an overview of *ILSA's domains and populations* (3.1) and their *assessments of contextual information* (3.2) and, second, illustrate their future directions. The following sections focus on the potential and innovative approaches of ILSAs with respect to the *types of data and data sources* (3.3) and the *methodological advancements* (3.4).

Domains and populations

Current status

The current status of **domains included in ILSAs** is rapidly changing. Currently, the main and oldest ILSAs (i.e., TIMSS, PISA, and PIRLS) focus on traditional cognitive domains, such as mathematics, science, and reading. However, the inclusion of new cross-disciplinary areas, such as problem solving, global competence, and financial literacy, is increasing. Especially PISA has lately included one new domain per cycle (see, for example, OECD, 2020b). In addition, there are new ILSAs that measure cross-disciplinary outcomes, such as ICILS measuring digital skills and computational thinking (Fraillon et al., 2020). Very few ILSAs measure other types of cognitive outcomes in domains beyond mathematics, science, and reading. For instance, DICE¹ measures the effects of educational theater and drama on five of the eight Lisbon Key Competences in a longitudinal EU-funded project in 12 countries (Gjærum et al., 2022; Cziboly, 2010).

The current status of **populations included in ILSAs** is also rapidly changing. Traditionally, the main ILSAs have targeted students in school. The target grades of TIMSS are grades 4 and 8, PIRLS includes only fourth graders, and PISA samples 15-year-old students. However, newer ILSAs include populations outside of school, such as PIAAC that includes adults, IELS that includes children in kindergarten, and TALIS that includes teachers. In addition, the inclusion of low- and middle-income countries in PISA and TIMSS has increased over the years (Rutkowski and Rutkowski, 2019; see also the chapter by Rutkowski and Rutkowski, 2022, in this encyclopedia). New regional studies and a new PISA study called PISA-D targets developing countries and strive to take into account the local context (Kamens and Benavot, 2011).

Future directions and needs

As education and society change, the **need for measuring new domains**, at least from the perspective of accountability, is increasing. There is a common understanding that students need other types of skills in the 21st century, and that these skills are more cross-disciplinary in nature (Griffin and Care, 2014). While some ILSAs already include some of these cross-disciplinary domains, there is still a need to extend these to include other key domains, for instance, creative thinking, self-regulation, or socio-emotional skills. Lately, democracy has been endangered in some countries (Afsahi et al., 2020); hence, the International Civic and Citizenship Education Study (ICCS) is becoming increasingly important (Schulz et al., 2018).

There is further a **need for better assessments**, both for those that have already been included as well as for possible future domains. There are many ways to improve the measurement of these domains, for instance, through computer-based assessment that would allow for interactive items, the collection and analyses of process data, and adaptive testing (see sections **Novel task and test designs** and **Utilizing process data from technology-based assessments**). At the same time, many cross-disciplinary skills might be hard to measure, such as emotional intelligence like empathy or real collaboration.

There is also a **need for including subject domains other than mathematics, science, and reading**, for instance, art subjects or history. Including other subject domains would provide a more holistic picture of students' competence and a more complete picture in terms of accountability. Moreover, operationalizing the outcomes in new subject domains entails research on curricula and theories underlying the subjects, which again could contribute to enhance the quality of the subjects. However, creating ILSAs that measure "everything" could compromise the validity of inferences. To use an analogy, there is a reason why there are different

¹Drama Improves Lisbon Key Competences in Education, <http://www.dramanetwork.eu/acknowledgements.html>.

types of airplanes, for instance one type for cargo, another to transport passengers, and a third for military purposes. Having one type of plane to cover all these needs, would not be efficient and would reduce the quality of the transport.

In terms of **populations**, ILSAs already cover pre-primary, school, to adult samples. Among other, a key challenge in terms of populations is the balance between high- and low-income countries, between developed and developing countries, or between Western and non-Western countries. ILSAs were primarily built on the theories and contexts of Western countries (Blömeke et al., 2022), and even though non-Western countries' voices are increasingly impacting the processes and decision-making around the development and implementation of the ILSAs, there is still a need to include these voices to a larger degree (Blömeke et al., 2022). Including theories and contexts of low- and middle-income countries is important. The regional studies may be a consequence and response of countries striving for an ILSA that takes into consideration the country contexts and cultures (Kamens and Benavot, 2011). Previous research (Rutkowski and Rutkowski, 2018, 2019; Rutkowski et al., 2018) demonstrated that the increased heterogeneous mix of countries participating in ILSAs is problematic for establishing achievement scales, as test items are not equally difficult across countries. This means that the validity of the achievement scale is threatened, and this is especially problematic at the ends of the scales. Hence, for the low-performing countries, the ILSA tests may not provide an accurate picture, and are of less value. This issue could be partly addressed in PISA-D and via adaptive testing (see **Novel task and test designs** section).

Assessment of contextual information

Current status

A **mutual relationship between research and ILSAs** exists, in that ILSAs inform research and vice versa (Blömeke et al., 2022). For instance, school climate is a broad construct that is defined differently across many studies (Wang and Degol, 2015). However, through consensus and feedback, the ILSAs have continuously improved their indicators of school climate (e.g., school safety, bullying, and students' sense of school belonging; Mullis and Fishbein, 2020; Mullis and Martin, 2017). Perhaps as consequence of a more clearly defined framework for school climate and of high-quality measures and data, many secondary analyses of school climate ILSA data have been published (Teig and Nilsen, 2022). In this way, ILSAs have generated research evidence and opportunities. At the same time, researchers influence the shaping of the ILSA constructs as part of expert groups (Mullis and Fishbein, 2020; OECD, 2019a). In addition, the frameworks are built on previous research (OECD, 2019a; Mullis and Martin, 2017). In other words, research contributes back to ILSAs and influences their development.

The **types of constructs and contextual information** included in the contextual questionnaires in ILSAs, is primarily guided by educational effectiveness on the one hand (Klieme, 2013), and policy and accountability on the other hand (Addey et al., 2017). Educational effectiveness is a field concerned with identifying factors that contribute to make a school "good" (e.g., student cognitive and affective outcome; Reynolds et al., 2014), and takes into account the dynamic nature and hierarchical design of educational systems (Creemers and Kyriakides, 2008). Other than including contextual information, ILSAs also include constructs and variables that may not be directly related to student outcomes, such as the availability of a laboratory at school (Mullis et al., 2020) and the content coverage in classrooms (Scheerens, 2016), but that would still inform the countries' accountability systems and policymaking.

Including new contextual information entails extending and revising the contextual frameworks. This is an ongoing process, and during this process the quality of the overall framework is often improved (Blömeke et al., 2022). Some constructs included in ILSAs have long had a solid foundation in theory, such as student motivation that is based on the Expectancy-Value Theory (Hooper et al., 2013; Eccles and Wigfield, 2002). Other constructs, such as teachers' instructional quality has been recently included, extended, and improved, utilizing the framework of the basic dimensions of teaching (Nilsen and Gustafsson, 2016; Kuger et al., 2016; Mullis and Martin, 2017; OECD, 2013). In section **Striving for good indicators of teaching practice: student ratings, teacher ratings, and observational classroom data**, we provide an example of how practices pointing to instructional quality are assessed.

Even though different ILSAs include different contextual information, there are some **key constructs and variables** that are similar across the studies and that align with educational effectiveness (Creemers and Kyriakides, 2008). To use TIMSS and PISA as examples, they both administer student and school leader questionnaires, and TIMSS, in addition, includes teacher questionnaires in both grades and parent questionnaires in grade 4. In the student questionnaires in these two studies, some of the key constructs and variables include student home background and characteristics (e.g., SES, minority, and gender), learning environment (e.g., school belonging, and bullying), perceptions of teachers' instructional quality, and student motivation. Key constructs and variables in the school questionnaires include principals' background and education, school climate (e.g., school safety and climate), and information about the school (e.g., characteristics of the neighborhood, school composition). Some of the key constructs and variables in the TIMSS' teacher questionnaire include teachers' formal qualifications and education, their experience, instruction, self-efficacy in teaching mathematics and science, job satisfaction, and the implemented curriculum (the degree to which the content in TIMSS framework has been taught). Key constructs and variables in the parent questionnaires include early literacy and numeracy of their child before attending school, background and characteristics of child and parent (e.g., SES and minority), and parents' attitudes toward school and to mathematics and science. Just like the test of students' cognitive outcomes, the contextual constructs and variables are subject to strict quality assurance procedures (Wagemaker, 2020). These procedures include feedback from the countries and expert groups, piloting, and psychometric evaluation to ensure high reliability and validity.

Future directions and needs

Although the underlying theory of constructs and variables in the contextual questionnaires has improved, there is still room for improvement (Blömeke et al., 2022). Measures for SES is a typical example of this and has been subject to much criticism (e.g., Rutkowski and Rutkowski, 2018). One of the major problems with SES and many other constructs in ILSAs, is that their conceptualizations and operationalizations may vary across cultures (van de Vijver, 2018). In PISA, for instance, one of the indicators of SES is whether students have their own room, and while this may help differentiate between low- and high-SES students in developing countries, it may not be the case for high-income countries. While much effort has been taken in psychometrics to ensure comparability of constructs across different cultures (see *Comparability of measures* section), there is still a need for the same type of effort within the theoretical foundation underlying these constructs.

Striving for good indicators of teaching practice: student ratings, teacher ratings, and observational classroom data

As ILSAs strive for describing contextual information about teaching and learning, assessing teaching practices has gained considerable importance. However, measuring teaching practices is not an easy task, given the heterogeneous mix of countries in ILSAs (see *Future directions and needs* section). Despite this challenge, it has become the hope to identify “effective” practices that have the potential to foster student learning and compare the occurrence of these practices across countries (Klieme, 2013). However, researchers are struggling with defining the practices that promote learning and motivation (Praetorius et al., 2018), and many different theoretical frameworks exist in different parts of the world (e.g., Praetorius et al., 2018; Kane and Cantrell, 2010; Ferguson and Danielson, 2015; Kyriakides et al., 2000). Indeed, most research within this area has been developed in Germany and the USA, and several studies have found that these frameworks may not create a good foundation for comparisons across different cultures (Blömeke and Olsen, 2019).

ILSAs have progressed toward including several indicators of teaching practices and examine their relations to educational outcomes (as indicators of educational effectiveness). As most ILSAs do not follow a strict experimental design, inferences on educational “effectiveness” are, nevertheless, limited to the description of relations among classroom, school, and student variables (Klieme, 2020).

Student and teacher ratings of teaching practice

Depending on the source of information (e.g., student or teacher ratings), measures of teaching practices may have different interpretations. For instance, while student ratings primarily represent individual perceptions, classroom-average student ratings represent shared perceptions and could be considered a classroom rather than an individual characteristic (Scherer et al., 2016). Marsh et al. (2012) argued that researchers targeting the effectiveness or benefits of some teaching practice for student achievement should consider the classroom level and aggregated student ratings rather than using the student and individual ratings at the individual level in their analyses. In this sense, variation between student ratings represents a form of measurement error. As such, student ratings of teaching practices reference the classroom and/or the teacher and operate at these levels.

Klieme (2020) cautioned that not all ILSAs qualify for addressing research questions on educational effectiveness and practice. For instance, although students were asked to indicate the frequency of core teaching practices, such as classroom management, teacher support, and cognitive activation in mathematics in PISA 2012, the sampling design of this ILSA does not allow for inferences on educational effectiveness per se. As PISA samples students and schools randomly in most participating countries (with some exceptions, such as Germany), the level at which student ratings of teaching practice operate (i.e., the classroom/teacher level) is not contained (Eriksson et al., 2019). In contrast, the sampling design of TIMSS 2019 (and, in fact, all TIMSS cycles) contains the classroom and teacher level, so that student ratings are meaningful and have the potential to represent teaching practices meaningfully. Similarly, TALIS 2018 assessed teacher ratings of teaching practices and conceptualized them as teacher-level variables. Already in the national extensions of TIMSS 2015 in Belgium (Flanders), Germany, and Norway, student ratings of teaching practices were included. Bellens et al. (2019) took a multilevel structural equation modeling approach to describe the structure of these ratings and made the classroom-average ratings the core of their investigation. The authors have found empirical support for the hypothesized three dimensions of teaching practices at both the student and the classroom level, thus crafting a validity argument (see Fig. 1A).

This example highlights the importance of establishing appropriate representations of teaching practice constructs and clarifying at which level of analysis they may operate. Aligning the levels of measurement and construct representations is a key direction in ILSAs’ striving for information about the link between teaching and learning (Stapleton et al., 2016).

Although student and teacher ratings of teaching practices are accessible in ILSA via background questionnaires, these ratings still represent only perceptions of the classroom activities or environment or self-perceptions of the implemented practices. In fact, some evidence suggests that student and teacher ratings can differ considerably, even in clear-cut practices, such as classroom management (Wagner et al., 2016). Moreover, ratings may be specific to the teaching domains, contents, and situations (Praetorius et al., 2014; Scherer and Gustafsson, 2015). These observations have led to some criticisms of the student and teacher ratings of teaching practices in ILSAs and called into question the validity of the inferences drawn from them (Klieme, 2020).

TIMSS 1995 and 1999 video studies

To address these issues and move beyond using student or teacher ratings as indicators of teaching practices, some ILSAs have initiated observational classroom studies. For instance, TIMSS 1995 and 1999 have been supplemented by video studies (Neubrand, 2006). The TIMSS 1995 Video Study examined the mathematics instruction of 231 German, Japanese, and US-American classrooms from nationally representative teacher samples. Besides its focus on developing and testing the methodology and feasibility of large-

Fig. 1 Multilevel Confirmatory Factor Analysis (MCFA) models with (A) cross-level configural and (B) cross-level metric invariance.

Note. B = Between (school) level, W = Within (teacher) level, A–L = Items measuring the constructs. Residual variances are omitted in the figure to improve the clarity of presentation.

scale classroom observations, this study also resulted in video vignettes to inform teachers, educators, and policymakers around the world. Extending the range of participating countries, the TIMSS 1999 Video Study captured classroom practices not only in mathematics but also in science classrooms. Among others, this study has shed light on the typical practices of teaching both subjects, how students are provided with opportunities to learn, the extent to which teachers support student learning and scientific practices. These two video studies have initiated a plethora of follow-up video studies at small and at large scale (e.g., Klette, 2016), and have shaped the development of methodological standards for assessing and operationalizing teaching practices in mathematics and science (Jacobs et al., 2007). Identifying the similarities and differences in classroom instruction has become a key interest (Stigler et al., 2000).

TALIS 2018 video study and Global Teaching InSights

As an extension of the TALIS 2018 study, the OECD has launched an international large-scale video study to shed light on (a) the types of teaching practices; (b) their interrelations; and (c) their relations to students' cognitive and non-cognitive outcomes (OECD, 2018). This study utilized an advanced video observation methodology, focusing on a single curricular unit and including a large and diverse teacher sample. This study implemented a longitudinal design with pre- and post-test measures of student achievement, student and teacher ratings of instruction, videotaped classroom lessons, and an evaluation of the teaching material. Besides the insights this study provides into the effectiveness and implementation of specific teaching practices, it provides rich material to evaluate and code classroom instruction. Selected video sequences are being made available for teachers, teacher educators, and researchers via a digital platform for supporting professional development, teacher training, and research projects (OECD, 2020a).

Types of data and data sources

International large-scale assessment data provide researchers and policymakers with many opportunities to evaluate educational systems nationally and internationally. Over the last two decades, ILSA data sources have been extended in several ways: Some countries utilized the data from multiple ILSA cycles to examine changes in educationally relevant constructs and indicators at the country or system level over time, and/or added longitudinal follow-up studies to examine such changes at the level of students, classrooms, or schools. Apart from these extensions, under certain conditions, the data from one ILSA could also be linked the data from another ILSA (e.g., TIMSS and PIRLS, PISA and TALIS) and to national data sources (Scherer and Gustafsson, 2015; Barth et al., 2021; Kaplan and McCarty, 2013). In the following, we describe these opportunities and trends and showcase their potential.

Linking multiple ILSAs

ILSAs vary in their sampling designs, assessment domains, and the levels at which information is extracted. Linking different ILSAs can therefore offer opportunities to examine the interrelations between unique and common assessment domains and to link data at multiple analytic levels.

Linking multiple ILSAs at the individual, classroom, or school level

There have been several occasions at which multiple ILSAs were administered in the same year. Some countries have utilized these occasions and linked different ILSAs, so that one data set can inform the other. Ideally, the sampling designs are aligned, and direct links between the different data sets can be established. However, if such direct links cannot be established, matching procedures may approximate them (Kaplan and McCarty, 2013). For instance, TIMSS and PIRLS were linked for fourth graders in 2011 (Martin and Mullis, 2013). This allowed researchers to examine the relations among student achievement in reading, mathematics, and science and contextual variables. Scherer and Gustafsson (2015) utilized this design and studied student ratings of teaching practices across the three domains at both the individual and the classroom level. Their study supported the domain specificity of student ratings, even for generic teaching practices—an insight that may not have been gained without this link. In other instances, researchers have utilized the possibilities for data fusion between PISA and TALIS (Gil-Izquierdo and Cordero, 2018), PISA and TIMSS (Carnoy et al., 2016), PIAAC and PISA (Meroni et al., 2015), and PIAAC and TALIS (Hämäläinen et al., 2021).

Linking multiple ILSAs at the country level

At the level of participating countries, many creative links between ILSAs can be established (Gustafsson, 2018). To ensure their validity, however, researchers need to pay close attention to the extent to which the corresponding data, measures, or effect sizes are comparable across ILSAs. If sufficient comparability can be established, integrative data analysis and meta-analysis provide a rich methodological repertoire to quantify the variation of empirical results across ILSAs, countries, and over time, and the evidence for the generalizability and replicability of phenomena (Cheung and Jak, 2016; Hedges and Schauer, 2019).

For instance, Keller et al. (2021) examined the nonlinear relations between students' academic self-concept and achievement and analyzed the data from 13 countries participating in TIMSS, PIRLS, and PISA for each study cycle separately. Once the relevant effect sizes had been extracted, the authors combined them across the different ILSAs via random-effects meta-analysis. These analyses resulted in overall effect sizes for different achievement domains and age groups and their respective variance components. In contrast to ordinary random-effects meta-analysis, in which two variance components are estimated, the linking of multiple ILSAs resulted in a more complex data structure with more variance components. Fig. 2 exemplifies such a structure for the domain of mathematics in Keller et al.'s study. Given that the 13 countries participated in multiple ILSAs and ILSA cycles, the meta-analytic data structure is *cross-classified*, that is, next to the level of effect sizes, the levels of countries and ILSAs co-exist independently (Fernández-Castilla et al., 2019). Generally, the combination of analyzing the ILSA data to obtain the effect sizes of interest and their meta-analysis across countries bear great potential for synthesizing findings and examining their generalizability.

Longitudinal designs and extensions of ILSAs

Longitudinal studies in education have the potential to shed light on learning gains, developmental processes over time, and their mitigating factors. Under certain conditions, such designs can aid the crafting of a causality argument (Rutkowski and Delandshere, 2016). In the context of ILSAs, trends in educational success and changes in performance in core educational domains may serve as direct accountability measures (Rutkowski et al., 2010). Two main approaches to generating longitudinal data have mainly been taken and developed further: (a) Longitudinal designs of ILSAs across cycles at the level of countries; and (b) Longitudinal extensions of ILSAs within countries.

Longitudinal ILSA designs at the country level

As many ILSAs repeat their cycles, countries are provided with information about the possible changes in educationally relevant constructs over time. These changes, however, may only be interpreted at the (aggregated) country level, if no direct link between the different ILSA cycles is established at the student, classroom, teacher, or school level. Interpretations along these lines should also account for possible linking error between ILSA cycles (Robitzsch and Lüdtke, 2019).

Fig. 2 Meta-analytic data structure quantifying heterogeneity between the ILSAs and 13 selected countries in mathematics.

Drawing from the evidence of more than twenty years of ILSAs, including PIRLS, PISA, and TIMSS, [Strello et al. \(2021\)](#) meta-analyzed the effects of early tracking and educational inequalities on student achievement. This study provided evidence that tracking may have increased achievement gaps in core educational domains over time. [Nilsen and Gustafsson \(2014\)](#) utilized the longitudinal design of TIMSS and studied the extent to which changes in students' science achievement were related to changes in schools' emphasis on academic success in Norway between 2007 and 2011. The authors found support for the mediating role of the schools' emphasis on academic success for the relation between the year of the TIMSS cycle and science performance, thus partly explaining performance changes. Extending this research to 38 countries participating in TIMSS 2007 and 2011, [Gustafsson and Nilsen \(2016\)](#) showed that differences in mathematics achievement and differences in aspects of school climate were related over time. These examples highlight the potential that lies within the country-level longitudinal designs of ILSAs.

Longitudinal extensions of ILSAs at the individual level within countries

Some countries have strived for extending ILSAs longitudinally at the individual participants' level. Such extensions provide rich information, as they make visible not only country-level but also individual-level changes over time ([OECD, 2013](#)). For instance, in Germany, a second measurement occasion has been added to PISA 2012, transforming this ILSA into a pretest-posttest study to examine achievement gains ([Nagy et al., 2016](#)). Similarly, the PIAAC 2012 cycle had been extended longitudinally ([Rammstedt et al., 2017](#)). Such extensions can provide evidence on the direct link between changes within variables over time and could inform value-added models in education ([Braun and von Davier, 2017](#)). Ultimately, these extensions are key future directions of ILSAs to inform educational practice, policymaking, and accountability ([OECD, 2013](#)).

Linking ILSA data to non-ILSA data

Exploiting the potential of ILSAs for accountability, many countries have aimed for linking them to national data, such as students' performance on national tests covering specific curricular content areas, register data on participants' pathways to their current profession, or official statistics on countries' economic development and innovation potential. As [Gustafsson \(2018\)](#) noted, the increasing availability of additional data sources provides researchers with "virtually unlimited possibilities for creative combinations of data which allow investigation of phenomena in several different disciplinary areas" (p. 332). In this way, it becomes possible to anchor the results of ILSAs in national contexts and to draw inferences that may aid national policymaking in education. Reviewing these attempts, we observed that ILSA data have mainly been linked to non-ILSA data at the individual, classroom, school, or national (country) level (see also [Strietholt and Scherer, 2018](#)). The following studies illustrate these links and their potential.

Bringing together ILSAs and national assessments

By and large, national and international assessments in education follow similar goals, such as monitoring students' proficiency levels and progress in core domains. While national assessments are oftentimes focusing on knowledge, skills, and other constructs in specific curricular domains or content areas, ILSAs cover knowledge, skills, and other constructs in cross-curricular domains or content areas relevant for a broad range of countries. In this sense, national assessments bear the potential to assess relevant educational outcomes more specifically tied to the national contexts—hence, linking ILSA and national assessment data can provide more contextual information about educational systems. For instance, [Jerrim et al. \(2019\)](#) linked the PISA 2015 data with the data from national assessments in England. This link provided evidence against the common belief that inquiry-based teaching practices in science are effective for fostering students' scientific literacy and science achievement. There was no support for the relation between the frequency of teaching scientific inquiry and performance on science exams, although this relation existed for the PISA science tests.

However, the designs, sampling procedures, and assessment characteristics may differ substantially between ILSAs and national assessments. Such differences necessitate studying the extent to which the two types of assessments may capture educational outcomes similarly. Linking the PISA 2012 data to the data of the German National Educational Panel Study (NEPS) at the student level, [Ehmke et al. \(2020\)](#) evaluated the comparability of the PISA and NEPS mathematics scores. Utilizing item response theory modeling, the authors found a high correlation between these scores ($r = 00.90$) and obtained further evidence for the correspondence between the two assessments. On the contrary, [Kampa et al. \(2021\)](#) provided some evidence that such a correspondence may not be a given. Specifically, they showed that a PISA scientific literacy test and a curricular-oriented science test from NEPS differed in the extent to which they assessed general and science-specific abilities. Overall, the linking of ILSA and national assessment data can aid the crafting of a validity argument for the national or international assessments.

Linking ILSA data to national registers

National register data can contain rich information about participants' educational pathways, academic success, employments, health, or wages. Linking these data with educational indicators derived from ILSAs could ultimately aid the study of lifelong learning and predictors of academic success at later stages in life. For instance, [Barth et al. \(2021\)](#) combined the Norwegian PIAAC 2011 data of young adults on numeracy and literacy with the registered GPA at age 16 and participants' employment and education two years after the PIAAC study. After controlling for indicators of home background, health status, and other variables, the authors found that GPA explained about 37 % of the variation in numeracy. Furthermore, GPA and the PIAAC scores were significantly related to later educational and economic success. This example highlights the value added by linking ILSA and register data.

Making sense of contextual information about countries

Studying the extent to which teachers' team innovativeness related to relevant teacher constructs, such as job satisfaction, teaching practices, and collaboration, Blömeke et al. (2021) analyzed the TALIS 2018 data from 48 participating countries and educational systems. In their study, the authors identified meta-analytically a substantial variation in the relationships among constructs across the countries. For instance, the contextual effect of teachers' shared perceptions of innovativeness in their schools on their individual satisfaction with the school environment ranged between $B = -0.10$ (small negative effect) and $B = 0.53$ (large positive effect). Similarly, the relations between perceived innovativeness and the extent to which teachers engaged in innovative teaching practices, for instance including technology and focusing on the teaching of 21st century skills, exhibited substantial between-country heterogeneity. In an attempt to explain this heterogeneity, Blömeke et al. (2021) extracted contextual information about the participating countries from additional data sources and examined whether the GDP per capita and the degree of individualism in a country moderated the innovativeness–teaching practices relation (see Fig. 3). While there was no evidence suggesting that GDP explained the variation between countries, there was evidence on the moderating role of individualism. Countries with higher scores on Hofstede's individualism scale were more likely to show a weaker innovativeness–teaching practices relation. Overall, about 25.4% of the variation could be explained. This example shows how additional context information can shed light on the possible sources or correlates of the variation between countries.

Once again, correlation is not causation

While the linking of ILSA data with external data sources can shed light on the “creative” relations between ILSA and non-ILSA measures in education (Gustafsson, 2018), the inferences drawn from such relations need to be treated with caution. At the country level, such inferences only represent correlations, yet not causation (Aldrich, 1995). For instance, a recent report on the status of school education after one year into the COVID-19 pandemic displayed the relationship between countries' average performance score on the PISA 2018 reading assessment and the number of days with full closures of upper secondary schools in 2020 (OECD, 2021). For the selected sample of countries, the relationship was negative, statistically significant, and corresponded to 54.1% of variance explanation. This observation, however, only showed that countries with lower average reading performance in 2018 *were likely* to experience school closures in 2020. Similarly, countries experiencing many school closures in 2020 were likely to be among the low-performing countries in PISA 2018 reading. Given the design of the PISA 2018 study and the nature of the school-closure data (e.g., different measurement occasions, different student and school samples as compared to PISA, 2018), inferences on poor learning outcomes causing disruptions of face-to-face learning or limited face-to-face learning in schools causing poor reading performance cannot be drawn. This example illustrates the need for carefully interpreting the links between ILSA and non-ILSA data and for communicating clearly which types of inferences can be drawn. Hence, researchers, educators, and policymakers should always consider the design and contexts of the respective studies providing these data.

Methodological advancements

Over the last two decades, international large-scale assessments have undergone major developments in their methodology. Especially with the advancements of technology, novel test and task designs have made their way into the ILSAs and have innovated the measurement of skills in the core and supplemental domains (Greiff et al., 2017). Besides these innovations, key issues of both the reliability of scores and the validity of the inferences drawn from these scores have been and are currently being addressed. These issues include but are not limited to the comparability of scales and their respective scores across countries and educational systems and the inclusion of information about test-taking behavior (e.g., Gustafsson, 2018; Schulz and Carstens, 2020; Beller, 2013).

Fig. 3 Relations between *logGDP*, individualism, and the teacher-level effect of perceived team innovativeness on innovative teaching practices. Note. Countries' three-digit ISO codes are shown in the figures. Based on the TALIS (2018) data.

Novel task and test designs

Novel task and test designs in ILSA are aimed at improving the assessments of core educational outcomes, which are ultimately used to inform accountability. At the same time, such designs make accessible “hard-to-measure” skills, such as collaboration, complex problem solving, or computational thinking (Greiff et al., 2017).

Innovative item and task formats

With the shift toward computerized testing, new items and task types have been made available. For instance, in the PISA 2012 problem-solving assessment, interactive items were included to assess students’ abilities to generate information about an unknown system and acquire knowledge about its functioning (OECD, 2014). These items required a direct interaction and could be used to trace students’ task-taking behavior in computer log files. Adding a component of collaboration, through which students could collaborate and communicate with an avatar, PISA 2015 assessed collaborative problem-solving skills—skills that would not have been accessible with paper-and-pencil tests. Similarly, PISA 2015 contained scientific inquiry tasks, in which students could explore the effects of varying one variable at a time in an experiment (Teig et al., 2020). These examples illustrate how the assessments of key educational constructs could be extended by computerized tasks.

Multi-stage adaptive testing

Utilizing the potential of adaptive testing and striving for improving the precision of proficiency estimates, some ILSAs, such as PISA 2018 and PIAAC 2012, have introduced multi-stage adaptive testing (MST). This test designs allows test-takers to take different testing routes, depending on their responses to a set of pre-defined items or tasks (Yamamoto et al., 2018). For instance, in the first PIAAC cycle, participants were first assessed in their digital skills and then routed to the assessments of literacy, numeracy, and problem solving. This way, participants with little or no computer experience could be directed to a paper-and-pencil test and/or interview to adequately assess their skills (Kirsch and Lennon, 2017). In PISA 2018, the digital reading assessment contained a set of core tasks which were then used to administer follow-up tasks. This MST design has the potential to improve measurement precision and keep the time students spend on the assessment reasonable. Alongside the development of MST designs, the psychometric models describing performance and directing the selection of items and tasks have also been advanced (Magis et al., 2017). Moreover, current research evaluates the optimal routing strategies to be implemented in ILSAs (Svetina et al., 2019).

Utilizing process data from technology-based assessments

As noted earlier, ILSAs are shifting toward technology-based assessments (Beller, 2013; Cresswell et al., 2015). This shift offers several opportunities to measure skills and to gain information about the task-taking processes via so-called log files—files that store the interactions and activities while participants work on tasks. The resultant process data can (a) inform test designers about the match between the intended and observed response processes to craft a validity argument (Pellegrino et al., 2016; Ulitzsch et al., 2021); (b) uncover systematic or unsystematic strategies or behaviors needed to solve problems (Greiff et al., 2015); (c) indicate the effort participants have spent while taking an assessment (Scherer et al., 2015); (d) explain why some test-takers succeed and other do not (OECD, 2015); or (e) improve the estimation of proficiency scores in test domains (Reis Costa et al., 2021).

Uncovering problem solving strategies and response behaviors

In PISA 2012, students’ complex problem-solving skills were assessed by interactive tasks, in which the information needed to solve the task had not been provided at the outset of the task. A typical example is the so-called “Climate Control” task, which contained three input variables and two outcomes (OECD, 2014). Hence, students had to interact with the task by manipulating variables systematically, observe the outcomes, and interpret them. This process of knowledge acquisition ultimately aids the development of a mental model about how input and outcome variables are related (Greiff et al., 2013). In their secondary analyses of the PISA 2012 data, Greiff et al. (2015) explored students’ problem-solving strategies, focusing on the Vary-One-Thing-At-a-Time (VOTAT) strategy. The authors found that students who performed this strategy were more likely to succeed with the overall problem-solving task, including the application of the knowledge acquired in an exploration stage. This way, Greiff et al. (2015) were able to classify students’ performance not only into successful or unsuccessful but also into systematic (i.e., following the VOTAT strategy) or unsystematic. The actions stored in log files uncovered the performance of this particular problem-solving strategy.

While the VOTAT strategy may be straightforward to identify, other strategies or sequences of actions may be more challenging to extract. To address this challenge, data-mining approaches are currently explored to make visible more complex test-taking behavior and their profiles (e.g., Qiao and Jiao, 2018; Han et al., 2019; Teig et al., 2020). While many of these approaches are exploratory, Goldhammer and Zehner (2017) cautioned that any process indicator extracted from log file data must undergo a validation process to facilitate meaningful inferences and interpretations.

Indicating test-taking effort

Process data can further provide information about test-taking effort and indicate motivation or achievement goals (Scherer et al., 2015). In recent years, the number of interactions with a task and the time spent on a task have served as indicators of these constructs (Goldhammer et al., 2020). In this respect, process data could provide ways of measuring test motivation beyond self-report scales. For instance, Pools and Monseur (2021) studied the relationship between test-taking effort and science achievement for the PISA 2015 data of six English-speaking countries. Utilizing students’ response times as indicators of effort, their study uncovered moderate to strong correlations, with increasing values toward the end of the test. Moreover, typical measures of

expectancy and value did not explain substantial variation in response times, thus questioning their correspondence. Hence, response times—key process data extracted from log files—can inform researchers and evaluators about the effort spent on the tasks and thus facilitate a nuanced interpretation of performance (Kroehne and Goldhammer, 2018).

Improving the estimation of performance scores

The information about test-taking behavior and effort can further inform the estimation of proficiency. Specifically, several indicators extracted from log files, such as response times, the number of actions, or the occurrence of specific strategies, may be used as variables informing the estimation of proficiency scores in the ILSA scaling models (Reis Costa et al., 2021) and modeling the processes underlying missing data (Pohl et al., 2019). For instance, in their study of the PISA 2012 interactive mathematics tasks, Reis Costa et al. (2021) showed that including information about the time students have spent on the computer-based tasks can improve the precision of the ability estimates and make visible country differences in response processes. Integrating process data into the ability estimates is a future direction of research on ILSAs that bears the potential to improve the current scaling models which form the basis for the inferences drawn in the context of accountability (von Davier et al., 2019a).

Comparability of measures

With the increasing number of countries and populations included in ILSAs, establishing the comparability of measures is key to crafting a validity argument (Rutkowski and Rutkowski, 2016). As a consequence, ILSAs have included analytic procedures to test for the invariance of the measurement models of important scales and indicators. These procedures are aimed at ruling out that observed country differences may only be due to the differential functioning of items or scales (Avvisati et al., 2019; Scherer, 2020). While perfect invariance is oftentimes not met, for instance due to culture-specific item formulations, several analytic options have been developed to retain some degree of invariance by including country-specific and common item parameters in the scaling (von Davier et al., 2019b).

Measurement invariance

Measurement invariance refers to the psychometric equivalence of construct representations (i.e., measurement models) and establishes the degree to which constructs have the same meaning across groups and/or over time (Putnick and Bornstein, 2016). Typically, measurement invariance is tested by specifying and estimating a sequence of measurement models with increasing equality constraints on the model parameters. These models are then compared to a baseline model, the *configural invariance model*, which establishes the same setup of the factor structure but freely estimates all model parameters across groups and/or over time (Millsap, 2011). Fig. 4 displays such a baseline model with three latent variables and two groups.

The subsequent invariance models constrain the factor loadings (*metric invariance*), factor loadings and item intercepts (*scalar invariance*), and factor loadings, item intercepts, and item residual variances (*strict invariance*). However, other combinations of constraints are possible and may shed light on additional degrees of invariance, such as the equality of factor means or (co-)variances (Marsh et al., 2009). These models are then compared to the configural invariance model or to other models with less constraints on the basis of goodness-of-fit indices (Chen, 2007; Rutkowski and Svetina, 2013). The respective guidelines and their specific application to ILSAs were discussed by Rutkowski and Svetina (2017). For instance, Scherer et al. (2016) and Bellens et al. (2019) tested the invariance of student ratings of teaching practice measures across countries, differentiating between three dimensions and utilizing the PISA 2012 and TIMSS 2015 data. Evaluating the above-mentioned invariance models, the authors found support for metric invariance and thus argued that structural relations among teaching practices, yet not the average levels (i.e., factor means) could be compared.

Approaches to invariance testing

Given the complexities of ILSA data, typical measurement invariance testing procedures, such as multi-group confirmatory factor analysis (MG-CFA) or multi-group item response theory (MG-IRT) models, reach their limits. As a consequence, psychometricians

Fig. 4 Multiple-groups measurement model with continuous observed variables.

have explored and developed alternative testing procedures, which may address these complexities. **Table 2** provides an overview of these procedures.

For instance, with many countries participating in ILSAs, MG-CFA and MG-IRT can hardly identify invariance levels beyond metric invariance. Hence, measurement invariance testing with many groups can be performed via multilevel CFA/IRT or alignment methods. [Marsh et al. \(2018\)](#) found that alignment methods can retain the comparability of factor means if scalar invariance fails. Next to these methods, other procedures provide information about item-specific differential item functioning ([Buchholz and Hartig, 2017](#)), the invariance along continuous variables ([Bauer et al., 2020](#)), or the invariance across initially unobserved groups ([Kim et al., 2017](#)). [Scherer \(2020\)](#) reviewed these procedures in greater detail and illustrated their implementation in the context of ILSAs. As the research on measurement invariance testing is continuing, new procedures may be developed which could examine and establish sufficient degrees of construct equivalence across a broad range of countries efficiently in the context of ILSAs. Such procedures are key to interpreting the results of ILSAs for accountability purposes.

Invariance of multilevel constructs

As noted earlier, some constructs have a meaning at multiple levels of analysis (e.g., classroom teaching practices assessed by student ratings). Hence, multilevel measurement models may exist, with model parameters that can vary between countries at different levels of analysis. As a consequence, the procedures of invariance testing have been extended to multilevel situations ([Ryu, 2014](#)). [Scherer and Gustafsson \(2015\)](#) evaluated the invariance of student ratings of teaching practices in reading, mathematics, and science for the TIMSS and PIRLS 2011 data across several countries and developed a testing framework with specific invariance testing steps. These steps include the testing of invariance across countries at the student level, the classroom level, and both levels at the same time.

Besides invariance across countries, another form of invariance is key to establishing the same meaning of constructs across levels of analysis, that is, cross-level measurement invariance ([Jak, 2019](#)). **Fig. 1** shows two models of multilevel confirmatory factor analysis (MCFA) that may describe the structure of multilevel constructs, such as teaching practices in classrooms. The configural cross-level invariance model (a) assumes the same setup of the factor structure across levels, and the metric cross-level measurement invariance model (b) assumes the same factor loadings across levels in addition. In a situation where multilevel constructs are compared across countries, both cross-country and cross-level measurement invariance are important to test and establish (e.g., [Blömeke et al., 2021](#)).

Despite these psychometric perspectives, the main perspective behind measurement invariance testing is to ensure valid inferences drawn from possible differences between countries or levels of analysis. Further research will develop the methodological approaches and assessment designs to improve the invariance testing procedures but also deal with situations in which full invariance cannot be established.

Table 2 Overview of selected invariance testing procedures applied to ILSA data.

Procedure	Description	ILSA examples
Multi-group CFA/IRT	Measurement models with a sequence of equality constraints on model parameters across groups	Rutkowski and Rutkowski (2013)
Multi-group ESEM	Exploratory structural equation models with a sequence of equality constraints on model parameters across groups	Scherer et al. (2016)
Multi-group Bayesian CFA/IRT	Measurement models with a sequence of equality constraints on model parameter distributions across groups and sensitivity analyses of model priors	Braeken and Blömeke (2016)
Alignment optimization	Approximation of scalar invariance by estimating group-specific factor means and variances	Glassow et al. (2021)
Alignment-within-CFA/IRT	Two-step procedure combining alignment optimization and multi-group CFA/IRT	Marsh et al. (2018)
Multilevel CFA/IRT	Multilevel measurement models utilizing the grouping as a level of analysis and testing random effects of model parameters	Fox and Glas (2016)
Moderated nonlinear factor analysis	Differential item functioning tests for (non-) linear moderation effects on model parameters of grouping variables and/or covariates (e.g., MIMIC-DIF models)	Chen and Hwu (2017)
Local SEM	Differential item functioning tests for (non-) linear moderation effects on model parameters at given points of grouping variables and/or covariates	Gnambs and Schroeders (2017)
Factor mixture modeling	Invariance testing for unobserved (latent) groups	Kim et al. (2016)

Note. MIMIC-DIF = Multiple Indicators Multiple Causes Model for Differential Item Functioning testing, SEM = Structural equation modeling.

Concluding remarks

To summarize, ILSAs include various *domains*, *populations*, and *contextual information*, yet could be further extended to improve the crafting of an accountability argument and ultimately provide countries with a more holistic picture of educational outcomes. Concerning the populations, longitudinal extensions and a balanced selection of countries could enhance the information gained from ILSAs substantially, informing educational effectiveness and cultural comparisons. With regards to contextual information, there is a need to further develop the theoretical foundation underlying constructs to be able to make meaningful comparisons across cultures. It is hence important that researchers from different cultures, from both Western and non-Western countries, contribute to developing the contextual questionnaires.

ILSAs provide rich *data sources* have benefitted from the *innovations in assessments* and *methodological advancements*. The novel task and test designs (e.g., innovative items, task formats, and multi-stage adaptive testing) are all aimed at assessing better constructs in the traditional domains and at making assessable new constructs that require interactions between test-takers and tasks, and among test-takers. The shift to computer-based assessments has facilitated the implementation of these innovations and have made available process data that can uncover problem-solving strategies, response behaviors, or test-taking effort. These data inform the crafting of a validity argument and have the potential to improve the estimation of achievement scores.

With these insights, we return to our question in the section: To what extent can ILSAs inform evidence-based decision-making and accountability? What is needed? Which developments can support these processes?

Certain characteristics and strengths of ILSAs enable them to fulfill their purpose on accountability. One such strength is their trend design which allows countries to monitor cognitive and affective outcomes as well as contextual information over time. In addition, comparisons across countries could, to a certain extent, be useful as they may provide some indication of success factors in educational systems. Internationalization may render countries that lag behind on ILSAs less fit for competition in the future, global job market. At the same time, comparisons of both outcomes and contextual information across countries need to be treated with caution. As has been discussed, there are major issues with the non-invariance of measures and indicators due to the heterogeneous sets of countries.

The comparative descriptions, for instance, of outcomes and contextual information over time, reflect the very strength of the ILSAs as the data are of high quality and based on representative samples. However, correlations between predictors and outcomes may not provide useful information on accountability, as drawing causal inferences on the basis of ILSA data is the least appropriate purpose with regards to accountability. That being said, we showcased how causal methods (e.g., differences in differences), longitudinal extensions of ILSAs, meta-analyses of ILSAs, and linking ILSAs with other data may enhance the validity and robustness of inferences. To this end, even correlations may be useful, especially with methods that allow for stronger and more robust inferences (e.g., multi-level SEM, differences in differences, or propensity score matching), but need to be interpreted with care. Here, ILSAs have a responsibility to inform stakeholders on how to interpret results, and researchers using ILSA data are responsible for valid and correct reports and interpretations of their findings. However, ILSAs should continue to play an important role for informing the accountability of educational systems, but not alone.

EDITORS IN CHIEF – BIOGRAPHIES

Robert J Tierney

Rob Tierney is an international educator whose passion is for developing research partnerships to address local literacy needs with educators in different countries. Rob began his career as a classroom teacher in Australia, then proceeded to work in the United States, Canada, Australia and China. He is Dean Emeritus and Professor Emeritus of Language and Literacy Education at the University of British Columbia, the former Dean and Honorary Professor of the Faculty of Education and Social Work at University of Sydney, and a Distinguished University Professor at Beijing Normal University. In the United States, he has served on the faculties of the University of Illinois, University of Arizona, The Ohio State University, Harvard University, and the University of California. Rob has written a number of books and numerous articles on literacy especially related to global issues, diversity, and literacy development. His most recent book was entitled *A History of Literacy Education: Waves of Research and Practice* published by Teachers College Press in 2021. During his tenure as an educator, he has served as the President of the International Literacy Association, President of the Literacy Research Association, an Editor for the *Reading Research Quarterly*, the President of the Association of Canadian Deans of Education/ L'Association Canadienne des Doyens et Doyennes d'éducation, as well on a number of committees and boards for professional groups and government and nongovernment

agencies. In addition, he has been involved on a range of groups on projects globally including in Africa and Asia including for UNESCO, Children's Television Workshop, and Apple Computer.

Fazal Rizvi

Fazal Rizvi is an Emeritus Professor of Global Studies in Education at the University of Melbourne, as well as at the University of Illinois at Urbana-Champaign. He is also a Visiting Professor at the Universities of Turku in Finland and Pretoria in South Africa. He has written extensively on issues of identity and culture in transnational contexts, globalization and education policy, and Australia-Asia relations. He has published widely, and his book, coauthored with Bob Lingard, *Globalizing Education Policy* (Routledge 2010) is used widely in courses around the world. A sequel to this book, *Reimagining Globalization and Education* (Routledge 2022) has been published recently. Fazal is currently researching educational reform in Bhutan. He is a Fellow of the Australian Academy of the Social Sciences, a past Editor of the journal, *Discourse: Studies in Cultural Politics of Education*, and a past President of the Australian Association of Research in Education.

**Kadriye Ercikan**

Kadriye Ercikan is Vice President of Research and Measurement Sciences at the Educational Testing Service and Professor Emerita at the University of British Columbia. She is responsible for ETS's foundational and applied research and psychometric support of ETS's major testing products and contracts, and the NAEP contract for ETS. Her research focuses on validity and fairness issues and sociocultural context of assessment. Her recent research includes validation of score meaning using response processes, use of response process data for comparing groups and examining fairness and validity of interpretation, and use of scores from artificial intelligence-based automated scoring.

Ercikan is a Fellow of the International Academy of Education. Her research has resulted in 6 books, 4 special issues of refereed journals, and over 100 publications. She was awarded the AERA Division D Significant Contributions to Educational Measurement and Research Methodology recognition for another

coedited volume, *Generalizing from Educational Research: Beyond Qualitative and Quantitative*

Polarization, and received an Early Career Award from the University of British Columbia. Ercikan has been selected to serve as the NCME Book Series Editor (2021–2026).

EDITORIAL BOARD

SECTION EDITORS

Jason Beech is Associate Professor (Global Policy) at the University of Melbourne and visiting professor at Universidad de San Andrés in Buenos Aires where he holds a UNESCO Chair in Education for Sustainability and Global Citizenship. He is senior researcher of the National Council for Scientific and Technical Research of Argentina (CONICET), and Associate Editor of *Education Policy Analysis Archives*. He has been a member of the Board of Directors of the Comparative and International Education Society (2014-2016). Jason has published extensively on the globalization of knowledge and policies related to education. He has also written and is passionate about the challenges of educating for global citizenship and a sustainable future. He has taught in several universities in the Americas, Europe and Australia.

Professor Qing Gu is Director of the UCL Centre for Educational Leadership and Professor of Leadership in Education. She is the Past Chair of the *British Association of Comparative and International Education* (BAICE), Co-Editor of *Teachers and Teaching: Theory and Practice*, Associate Editor of *International Journal of Educational Development*, a member of the Research Standing Committee of the World Council of Comparative Education Societies (WCCES), and a member of the Research Evidence and Impact Panel for the Leadership College for UK Government. Professor Gu has directed and codirected many government and research council funded projects in the areas of teacher professional development, school improvement, and systemic reform and change. She has led a £1.9 m UK Economic and Social Research Council (ESRC) funded project *Schools as Enabling Spaces to Improve Learning and Health-Related Quality of Life for Primary School Children in Rural Communities in South Africa*. Some of her books have been translated into Chinese, Japanese, and Spanish.

Professor Smith is a New Zealand Maori of Te Aitanga a Hauiti, Ngati Porou, Kati MamoeNgati Apa, Ngati Kahungunu descent. He is a highly regarded and internationally recognized, Maori educationalist and scholar. He has been at the forefront of transforming Maori and Indigenous social, economic and cultural conditions through re-developing education and schooling outcomes. His work links theoretical thinking and practical applications within an ongoing cycle of transforming praxis.

Professor Smith trained as a teacher at Auckland Teachers College and taught in Auckland schools. He also lectured in Education at the Auckland College of Education. He was one of the first teachers and developers of a Kura Kaupapa Maori, an alternative, Maori philosophy and principles-based School. These Maori immersion schools have grown from a single entity in 1988 to over seventy-five publicly funded schools in 2015. His theoretical leadership in the Education Department at the University of Auckland helped inform the emergence of Maori Education as a distinct field of study across the New Zealand Tertiary Sector. This work has encouraged a wide range of academic studies focused on overthrowing persisting inequities within and as a result of education and schooling in New Zealand. His significant contribution to New Zealand education is to be seen in his work related to Kaupapa Maori as a theory of Transformative Praxis. All of these elements derive from his PhD research entitled, "The Development of Kaupapa Maori: Theory and Praxis (1997)".

Professor Smith's later academic work centered on developing theoretically informed strategies related to transforming high and disproportionate levels of Maori cultural, political, social, educational, and economic marginalization. He has been a significant scholar involved in the emergence of Tribal "university" institutions (Wananga) and is the former foundation Chair of the Council for Te Whare Wananga O Awanuiarangi. He led the successful Treaty of Waitangi Claim and settlement for Awanuiarangi. In his former position as Pro Vice Chancellor (Maori) at the University of Auckland, he was responsible for developing significant structural change within the institution while working within the Office of the then Vice Chancellor, Dr. John Hood. Notable achievements included implementing a Maori development strategy within the University which required all Deans to be responsive in their performance results for Maori and Pacific advancement; the oversight of the Proposal and winning of a National Centre of Research Excellence (Nga Pae o te Maramatanga); the initiation of the Maori and Indigenous doctoral program aimed at creating 500 Maori PhD graduates across the country in five years; the recruitment of top Maori academic scholars into the University of Auckland; the development of Kaupapa Maori as a theory of transformative praxis and which has had national and international influence. Professor Smith also served on the University of Auckland Council for three years as the Professorial representative for Academic staff.

In 2007 Professor Smith accepted a role as the Universitas 21 Distinguished Visiting Professor in Indigenous Education hosted by the University of British Columbia (within the Faculty of Education). Although the position was initially intended for two years, the role was extended for a further three years. While situated at the University of British Columbia, Professor Smith also chaired the Educational Policy Studies Department for three years. These positions allowed engagement with many Canadian universities as well as other universities across the world.

Professor Smith has made significant contributions to the political, social, economic, and cultural advancement of Maori and indigenous communities in New Zealand and around the Pacific Rim. He has worked extensively with other Native/Indigenous/First Nation's peoples across the world, including in Canada, India, US mainland (including extensive work in Hawaii and Alaska), Norway, Taiwan, Chile, Australia, as well as with selected Micronesian and Pacific nations. He is a regular contributor to national and international forums and conferences. Professor Smith has been an authoritative voice within the critical debates on *social, cultural and economic inequality* both in New Zealand and abroad, and he maintains a strong influence in the Maori/Indigenous languages revitalization movements.

Professor Smith stepped down from the administrative position of CEO/Vice Chancellor at Te Whare Wananga o Awanuiarangi in 2015 after eight years in the role. He resumed his academic research and writing career. In 2019 he was invited to take up a special Chair – Te Toi Ihorei ki Purehuroa – A "distinguished Professorial position at large" established for him at Massey University.

Professor Smith has been recognized and honored for his international contributions, receiving an Honorary doctorate (D.Litt.) from the Okanagan University College in 2005, and an Honorary doctorate (LLD) from the University of Northern British Columbia in 2013; he was elected as a Fellow of the American Education Research Association in 2014, and was awarded a Queens Honour – a CNZM in 2014. He was given the Prime Minister's Life-time Achievement Award (2017); and received the Te Ururangi National Award for Education (Matariki Awards, 2019).

Professor Smith is married to Professor Linda Tuhiwai Smith and they have one daughter and two mokopuna (grandchildren).

Therese N. Hopfenbeck is Professor of Measurement Analytics in the Melbourne Graduate School of Education, The University of Melbourne. Before starting her position in Melbourne, she was Professor in Educational Assessment and Director of the Oxford University Centre for Educational Assessment. She is a Visiting Fellow at Kellogg College, University of Oxford, elected Vice-President of *The Association for Educational Assessment-Europe* and Lead Editor of the journal *Assessment in Education, Principle, Policy and Practice*. Dr. Hopfenbeck's research agenda focuses upon bridging research on self-regulation and classroom-based assessment and making sense of international large-scale studies in education. In collaboration with Professor Nancy Perry, University of British Columbia, she is currently leading an international network of researchers disseminating classroom-based research, funded by Social Sciences and Humanities Research Council of Canada (2020–2022). She is also currently Principal Investigator for two research projects funded by IB, on critical thinking in PYP schools internationally and evaluation of education reforms in Kent, UK (2020–2022). In 2020, she led the research on Critical Thinking in the Diploma Program in Australia, England, and Norway (<https://ibo.org/research/outcomes-research/diploma-studies/critical-thinking-skills-of-dp-students/>). Dr. Hopfenbeck was Principal Investigator for the PISA (2022) study in England, Northern Ireland, and Wales, in collaboration with Pearson UK (2018–2023). She was the Research Manager of PIRLS (2016), funded by The Department of Education, UK.gov, and Principal Investigator of a major ESRC-DFID research study, Assessment for Learning in Africa (ES/N010515/1) (2016–2019). Since coming to Oxford in 2012, she has been the recipient of funding from ESRC-DFID, OECD, The Norwegian Research Council, Education Endowment Foundation, State Examinations Commissions Ireland, Jacob Foundation, and the International Baccalaureate totaling more than £2 mill in addition to a single grant of £4 mill in collaboration with SLATE: Centre for the Science of Learning & Technology at the University of Bergen, Norway. Prior to her appointment at Oxford, she worked as a postdoctoral researcher at the University of Oslo's research group for Measurement and Evaluation of Student Achievement at the Unit for Quantitative Analysis of Education (2010–2011). She is Adjunct Professor of the Norwegian University of Science and Technology (NTNU), member of the Visiting Panel for Research at the Educational Testing Service (ETS) in Princeton, expert member of the PISA (2022) Questionnaire Framework group, appointed by ETS and OECD (2014–2023). She has advised on the implementation of formative assessment programs in India, South Africa, Norway, and the Emirates and carried out policy work for UNESCO/OECD and the Norwegian Ministry of Education Norway. Therese has a presence on LinkedIn, ResearchGate, [Academia.edu](https://www.academia.edu/), and Twitter: @TNHopfenbeck.

tion, [UK.gov](https://www.uk.gov/), and Principal Investigator of a major ESRC-DFID research study, Assessment for Learning in Africa (ES/N010515/1) (2016–2019). Since coming to Oxford in 2012, she has been the recipient of funding from ESRC-DFID, OECD, The Norwegian Research Council, Education Endowment Foundation, State Examinations Commissions Ireland, Jacob Foundation, and the International Baccalaureate totaling more than £2 mill in addition to a single grant of £4 mill in collaboration with SLATE: Centre for the Science of Learning & Technology at the University of Bergen, Norway. Prior to her appointment at Oxford, she worked as a postdoctoral researcher at the University of Oslo's research group for Measurement and Evaluation of Student Achievement at the Unit for Quantitative Analysis of Education (2010–2011). She is Adjunct Professor of the Norwegian University of Science and Technology (NTNU), member of the Visiting Panel for Research at the Educational Testing Service (ETS) in Princeton, expert member of the PISA (2022) Questionnaire Framework group, appointed by ETS and OECD (2014–2023). Therese has a presence on LinkedIn, ResearchGate, [Academia.edu](https://www.academia.edu/), and Twitter: @TNHopfenbeck.

Nataliya Ivankova, PhD, MPH, is Professor in the School of Health Professions at the University of Alabama at Birmingham (UAB). As an applied research methodologist working at the intersection of mixed methods, qualitative, community-based, action, and translational research, she is internationally recognized for her empirical and methodological publications. She shares her research expertise through teaching mixed methods and qualitative research courses, conducting workshops and guest lectures, mentoring doctoral students and junior faculty, and serving as key personnel on funded research projects. At UAB, she directs an online graduate certificate program in *Applications of Mixed Methods Research* and oversees the design and analytical aspects of qualitative and mixed methods studies through the Center for Health Informatics for Patient Safety and Quality. She is a founding Coeditor of the *Mixed Methods Research Series* (Sage) and serves as an Associate Editor for the *Journal of Mixed Methods Research*.

Professor Jahnke is Director of Toi Kura Centre for Maori & Indigenous Education. She was the 2019 inaugural Toi o Te Wananga Fellow. Professor Jahnke holds professional qualifications in education and is cofounder and immediate past Chair of the Indigenous Peoples of the Pacific Special Interest Group of the American Education Research Association (AERA). She currently serves on the AERA Executive Committee. She was a member of the Social & Human Sciences Sub Commission of the NZ National Commission for UNESCO, the NZ Bioethics Council, the NZ Ethics Committee on Assisted Reproduction Technology, and Chair of NZ Health Research Council Ethics Committee. She is currently Cochair of the Aotearoa Research Ethics Board and a Fulbright Scholar.

Berit Karseth, PhD, is Professor at the University of Oslo, Department of Education. Karseth's main research and publications lie in the field of education policy, reforms, and curriculum studies. She has edited four books and written several journal articles and book chapters in both Norwegian and English. Her most recent publications in English include articles published in the *Journal of Education Policy*, *Scandinavian Journal of Educational Research*, *Journal of Curriculum Studies*, and *European Educational Research Journal*. Karseth was the elected dean of the Faculty of Educational Sciences at the University of Oslo 2013–2016 and is currently in the leadership team of the research group Curriculum studies, educational leadership, and governance (CLEG) at the same institution.

Dr. Kenneth Leithwood is Emeritus Professor at OISE/University of Toronto and an honorary professor at the University College London and the University of Nottingham. His research and writing is about school leadership, educational policy, and organizational change. He has published extensively on these topics. For example, his most recent books include *Leadership Development on a Large Scale: Lessons for Long-term Success* (2018, Corwin), *How School Leaders Contribute to Student Success* (2017, Springer), and *Linking Leadership to Student Learning* (2012, Jossey Bass). Professor Leithwood is the inaugural recipient of the University of Toronto's *Impact on Public Policy* award, AERA (2011) *Outstanding Leadership Researcher Award*, the 2012 *Roald F. Campbell Lifetime Achievement Award* from the University Council for Educational Administration, and the Ontario Principals' Council *Outstanding Educator of the Year* award for 2017. He is a *Fellow of the Royal Society of Canada*. A recently published bibliometric analysis found that Dr. Leithwood was the most frequently cited, highest impact educational leadership researcher in the world.¹ Research.com's 2022 Ranking of the Top 1000 Scientists in the area of Social Sciences and Humanities ranked Dr. Leithwood 70th in the world and 7th in Canada.

Xiufeng Liu is a Professor of Science Education at State University of New York, Buffalo, and a Fellow of the American Association for the Advancement of Science (AAAS). He obtained his PhD from the University of British Columbia in 1993. Before his current position, he taught high school chemistry in China, and was a tenured faculty member at St. Francis Xavier University and University of Prince Edward Island, both in Canada. From September 2020 to August 2022, he served as a program director in the Division of Research on Learning of the National Science Foundation. Dr. Liu conducts research on measurement and evaluation of STEM education and student learning of cross-cutting concepts of matter and energy. Dr. Liu is currently a Coeditor-in-chief for the journal *Disciplinary and International Science Education Research* (Springer) and an Associate Editor for the *Journal of Research in Science Teaching*, a premier journal in science education.

Margie Maaka is a Professor of Education at the University of Hawai'i at Mānoa. Her PhD is in educational psychology. She also holds professional qualifications in education from the University of Waikato and Hamilton Teachers College. She is cofounder and current Program Chair of the Indigenous Peoples of the Pacific Special Interest Group (SIG) of the American Educational Research Association (AERA). From 2017 to 2020, she served as a member of the AERA Executive Council and Chair of the SIG Executive Committee. Before that (2014–2017), Professor Maaka served as a member of the SIG Executive Committee. She has also served as a member of the Ngā Pae o te Māramatanga Center of Research Excellence International Research Advisory Panel. Her research on community-based educational renewal saw her recognized as a national scholar with the Goodlad Institute for Educational Renewal. As Cochair of the Sovereign Councils of the Hawaiian Homelands Assembly's Committee on Education, she prepared educators and educational leaders for public schools in the Hawaiian Home Lands Trust communities. Currently, Professor Maaka is committed to the preparation of indigenous educational leaders in higher education. Her research interests include community partnerships, educational psychology/indigenous educational psychology, indigenous development and advancement, educational policy, multiliteracies, and language and cognitive development.

Diane Mayer is Professor Emerita at the University of Oxford. Her research and scholarship focus on teacher education and early career teaching, examining issues associated with the policy and practice of teachers' work and teacher education.

Daniel McCaffrey is the Associate Vice President of Psychometric Analysis and Research in the Research and Measurement Science unit of the Research and Development division at ETS. Dan's research interests include the evaluation of artificial intelligence scoring of constructed responses, developing tools and methods for causal modeling, evaluating the psychometric properties of student achievement growth measures derived from annual test scores, and methods to account for measurement error in secondary data analysis. Dan received his PhD in Statistics from North Carolina State University in 1991.

Judy Parr is Professor Emerita at the University of Auckland, Faculty of Education, where she was the founding Head of the School of Curriculum and Pedagogy. A psychologist, Dr. Parr's research program is located broadly within improvement science. Her expertise is in literacy, specifically writing and its development, encompassing instructional issues like teacher knowledge and practice and the assessment of writing. Much research has been collaborative, with colleagues and practitioners within major national projects for school improvement aimed at raising achievement in literacy and, internationally, as part of funded large-scale research projects, for example in Canada and Norway. Dr. Parr has published widely in the areas of literacy, assessment, and professional learning.

Jeong-eun Rhee is a Professor of Education, Long Island University, Post, New York. Born and raised in Seoul, Korea, she earned her bachelor's degree in Educational Psychology from Ewha Women's University. In 1992, she came to the US as an international student and received an MA in Educational Psychology from West Virginia University and a PhD in Educational Policy and Leadership from the Ohio State University. As an interdisciplinary cultural researcher and educator, her recent work focuses on developing and supporting transnational, intergenerational, and decolonial feminist knowledge projects in/through antioppressive education. She recently published *Decolonial Feminist Research: Haunting, Rememory, and Mothers*, which received an honorable mention for the 2022 Qualitative Book Award of International Congress of Qualitative Inquiry.

Fazal Rizvi is an Emeritus Professor of Global Studies in Education at the University of Melbourne, as well as at the University of Illinois at Urbana-Champaign. He is also a Visiting Professor at the Universities of Turku in Finland and Pretoria in South Africa. He has written extensively on issues of identity and culture in transnational contexts, globalization and education policy, and Australia-Asia relations. He has published widely and his book, coauthored with Bob Lingard, *Globalizing Education Policy* (Routledge, 2010), is used widely in courses around the world. A sequel to this book, *Reimagining Globalization and Education* (Routledge, 2022), has been published recently. Fazal is currently researching educational reform in Bhutan. He is a Fellow of the Australian Academy of the Social Sciences, a past Editor of the journal, *Discourse: Studies in Cultural Politics of Education*, and a past President of the Australian Association of Research in Education.

Theresa Rogers is Professor of Language and Literacy Education at the University of British Columbia. Her research interests include youth arts, media and critical literacies, adolescent literature, and teacher education in literacy. Most recently she published "Youth Activism through Critical Arts, Transmedia, and Multiliteracies" in the *Oxford Research Encyclopedia*. She is author of the book, *Youth, Critical Literacies and Civic Engagement: Arts, Media and Literacy in the lives of adolescents* (Routledge) and numerous articles in scholarly journals such as *Literacy Research: Theory, Method and Practice*, *Reading Research Quarterly*, *Pedagogies*, *Language Arts*, *Children's Literature in Education* and *Journal of Literacy Research*. See: <https://ubc.academia.edu/TheresaRogers>.

Professor Chika Sehoole is a Professor of Higher Education and the Dean of the Faculty of Education at the University of Pretoria. He obtained his PhD at the University of the Witwatersrand, Johannesburg, in December 2002. In 2003/4 he was a visiting Rockefeller postdoctoral fellow at the Centre for African Studies at the University of Illinois in Urbana Champaign. In 2005/06 he was a New Century Fulbright Fellow, again, at the same university. His research interests are in the areas of higher education policy, internationalization of higher education, higher education in Africa, and teacher education. He has served in several international research projects focusing on higher education and providing expertise from the South African and African perspectives. In 2013–2017 he served as the Chairperson of the Board of the African Network for Internationalisation of Education (ANIE). He currently serves as the chairperson of the Education Deans' Forum of South Africa. He has published a singled authored book titled "Democratising higher education policy, constraints of reform in post-apartheid South Africa" by (Routledge); three edited scholarly books on higher education and more than 40 articles in journal articles, book chapters, and popular media.

Roland Sintos Coloma is a tenured Full Professor of Teacher Education at Wayne State University in Detroit, Michigan. A scholar of history, cultural studies, and education, his research addresses critical questions of race, gender, and sexuality from transnational and intersectional perspectives. His publications include *Asian Canadian Studies Reader* (2017), *Filipinos in Canada: Disturbing Invisibility* (2012), and *Postcolonial Challenges in Education* (2009). His articles have been published in top-ranked peer-reviewed journals, including *Curriculum Inquiry*, *Discourse: Studies in the Cultural Politics of Education*, *Educational Studies*, *Educational Theory*, *History of Education Quarterly*, *International Journal of Qualitative Studies in Education*, *Paedagogica Historica*, and *Race Ethnicity and Education*. He has successfully garnered over \$2 million of external funding from federal, education, and nonprofit agencies, including the US Department of Education, National Education Association, Spencer Foundation, and Schultz Family Foundation as part of the Bill & Melinda Gates Foundation's Grand Economic Challenges. Roland has served in various university leadership roles as an assistant dean, department chair, graduate coordinator, and center codirector. He was president of the American Educational Studies Association (2018–19), editor of the *Educational Studies* journal (2014–17), and program cochair of Division G (Social Context of Education) in the American Educational Research Association (AERA). He received the 2017 Distinguished Scholar Award from the AERA Research on the Education of Asian Pacific Americans SIG and the 2015 Article of the Year Award from the AERA Queer Studies and Education SIG. In 2020, he was appointed to the Governor of Michigan's statewide Asian Pacific American Affairs Commission. Born in the Philippines and raised in California, he completed his PhD in Cultural Studies in Education and Minor in African American and African Studies from The Ohio State University in 2004.

Roger Slee is the Founding Editor of *The International Journal of Inclusive Education* and *The Journal of Disability Studies in Education*. A former Deputy Director-General of Education in Queensland, Australia, he has advised governments on inclusive education policy and practice. His published books include: *The Irregular School*; *Inclusive Education Isn't Dead, It Just Smells Funny*; and *Ethics and Inclusive Education: Disability, Schooling & Justice* (with Gordon Tait). Roger was commissioned by the UNESCO to write the scoping paper for the 2020 Global Education Monitoring Report, *Inclusion and Education*. Roger also held the Chair of Inclusive Education at the Institute of Education, London, and is now the Diamond Jubilee Professor of Disability & Inclusion in the School of Sociology & Social Policy at the University of Leeds.

Ninni Wahlström is a Professor of Education at Linnæus University, Sweden. Her current research focuses on transnational and national policy discourses and their implications for national curriculum and classroom teaching from a perspective of curriculum theory and educational philosophy. Most recent publications are "School and democratic hope: the school as a space for civic literacy" in *European Educational Research Journal* (2022) and Wahlström (Ed.) *Equity, Teaching Practice and the Curriculum*, Routledge (2022).

Lei Wang is Professor and PHD advisor of the Institute of Chemical Education, the College of Chemistry in Beijing Normal University (BNU). She is also the member of Teaching Steering Committee on Basic Education of Ministry of Education of China and the director of its branch Committee on Secondary Chemistry Education, the director assistant of Faculty of Education of BNU, vice director of the Institute of Science Education of BNU, and Chairman of the Chemistry Education Committee of the Chinese Chemical Society. She is one of the chief experts in developing the *Secondary School Chemistry Curriculum Standards* of MOE. She works as the chief editor of high school chemistry textbooks (Shandong Science and Technology Press, 2004 and 2019 editions) and junior high school chemistry project-based learning textbooks (Shanxi Education Press, 2018 edition). She achieved the first prize of the National Basic Education Teaching Achievement Award, the second prize of the National Higher Education Teaching Achievement Award, and the BAOGANG Education Outstanding Teacher Award.

Everard Weber is a retired professor. He has worked in the field of education for more than 40 years. Currently he is a research associate at the University of Johannesburg (UJ) and an academic advisor in the Future Professors Programme (FPP) at UJ. He studied African Languages and History at the University of Cape Town and Comparative and International Education at Harvard University. In South Africa he has worked at Crestway High School in Cape Town, the University of the Witwatersrand, and the University of Pretoria. A recent book is *A home away from home: a community of international and South African university students*. The FPP is a government-sponsored initiative that seeks to develop the next generation of professors and academic leaders in all disciplines, across all universities in South Africa. He is in addition presently conducting fieldwork on curriculum change in South African higher education with Professor Shireen Motala and Dr. Venise Joubert at UJ. This project is grounded in the history of southern Africa and hopes to contribute to the scholarship of postcolonialism.

Ian A.G. Wilkinson is Professor in the Department of Teaching and Learning at The Ohio State University and Honorary Professor in the School of Curriculum and Pedagogy at the University of Auckland, Aotearoa/New Zealand. He has a background in educational psychology with special interests in cognition, instruction, and research methodology as they relate to the study of literacy. He served as coauthor of the influential report, *Becoming a Nation of Readers* (National Academy of Education, 1985). He was Co-Editor of *Reading Research Quarterly* from 2006 to 2012 and was inducted into the Reading Hall of Fame in 2021. His research examines the impact of classroom discussion and dialogue on students' reading comprehension and argument literacy and the implications for professional development of teachers. Recently he coauthored books include *The Most Reasonable Answer: Helping Students Build Better Arguments Together* and *Quality Talk About Text: Discussion Practices for Talking and Thinking About Text*.

David B. Yaden, Jr., PhD, is the *Jewell M. Lewis Endowed Distinguished Professor of Literacy* in the Department of Teaching, Learning and Sociocultural Studies at the University of Arizona. Prior to his present position at the University of Arizona, he held appointments at Emory University, the University of Houston, and the University of Southern California. He served as Co-Editor of the *Journal of Literacy Research*, one of the premier research journals in the field of literacy studies, and was a Principal Investigator in the federally funded Center for the Improvement of Early Reading Achievement (CIERA) where he implemented an early literacy curriculum for linguistically diverse preschoolers in inner-city Los Angeles. He also directed a statewide consortium of researchers from Arizona's major universities in the evaluation of the state's early childhood initiative to evaluate health, developmental, and educational factors contributing to school readiness. His research interests and specializations include developmental issues in early childhood education, the acquisition of literacy and biliteracy in young emergent bilingual children, family literacy, theories of reading disability, microgenetic research design, and the application of complex adaptive systems theory to growth in reading and writing.

Volume 14: Quantitative Research and Educational Measurement

Daniel F McCaffrey

© 2023 Elsevier Ltd. All rights reserved.

Introduction

The chapters that follow in Volume 14, *Quantitative Research and Educational Measurement*, present an overview and introduction to these two foundational areas of education research and practice. Quantitative research consists of “explaining phenomena by collecting numerical data that are analyzed using mathematically based methods (in particular statistics)” (Creswell, 1994). This short description captures the two fundamental elements of quantitative research: data and analysis using mathematical or statistical methods. The data and analysis are meant to support *empirical statements*, i.e., statements expressed in numerical terms that are about what “is” the case in the “real world” rather than what “ought” to be the case (Cohen and Manion, 1980). The unique feature of quantitative research is its systematic use of data to derive conclusions. Quantitative research studies are designed so that the data and analysis offer an accurate description of the real world and with samples that are large enough to provide conclusive evidence concerning hypotheses about the world. Typically, the statistical analysis methods used in quantitative research allow the researchers to assess the level of uncertainty or error in the empirical results and provide a measure of confidence in any hypotheses tested with the data.

Quantitative research is important because it provides insights not offered by other types of research. Quantitative research in education is used to test theories against the real world, whereas qualitative research typically is seen as generating hypotheses and theories about “how” the phenomena develop, progress, and exist. Theories are based on human interpretations and understandings of how the world works. Theories must be tested against the world and updated and revised. The empirical methods of quantitative research are needed for such tests. Quantitative research draws conclusions from the empirical analyses and studies are designed to test hypotheses with confidence not to generate them (Queirós et al., 2017).

Quantitative research is a massive topic area that encompasses all educational research involving quantitative data and methods. To provide a manageable introduction to this topic, we narrowed the focus of Volume 14 to statistical methods and educational measurement. These two areas cover the two fundamental elements of quantitative research: data and analysis.

“Modern problems and needs are forcing statistical methods and statistical ideas more and more to the fore” (Garrett, 1926, p. v). The sentiment captured by Henry Garrett almost 100 years ago is probably even truer today. With the ever-growing availability of data and empirical results, an understanding of the foundations of statistical methods has been and remains essential for any educational researcher or practitioner. The discipline of statistics methods is itself a large topic area with many subdisciplines and lines of research. Because the focus of the Encyclopedia is education, we restricted the entries on statistical methods and models that are pertinent to educational research and applications.

The other fundamental component of quantitative research is data. As Sukamolson (2007) notes, a challenge to quantitative education research is the fact that many of the phenomena of interest in education such as students’ knowledge, attitudes, or beliefs do not occur in the form of “naturally” quantitative data. The field of educational measurement arose to overcome this need by providing statistical methods, theories, and practices to collect data on educational outcomes of interest. Like statistical methods, the practice of measuring student knowledge has a long history dating back to the mid-19th century in the England (Clauser and Margolis, 2022).

Educational measurement and statistical methods are overlapping fields. Educational measurement is an application of the general statistical approach:

- a. Collect data related to question of interest or to support a decision;
- b. Analyze and summarize the data;
- c. Using the laws of probability and assumptions about the relationship between the data and the question of interest, draw conclusions from the data including measures of uncertainty about inferences.

However, the discipline of statistics, even restricted to methods used in educational research and practice, entails far more than the models and methods used in educational measurement. Additionally, educational measurement fundamentally is more than simply a branch of statistics. There are unique foundational issues underlying measurement, particularly for the unique attributes measured in educational applications. Educational measurement not only entails the analysis of the data but also includes the theory and practice of collecting measurements through educational testing or assessments. Furthermore, educational measurement is not an abstract field of research. It involves drawing inferences about humans engaged in educational endeavors and the educational systems that support them. Educational measurements can have profound impacts on individuals and educational policies and practices. Consequently, the research on educational measurement goes beyond the mathematics of psychometrics and abstract theories on the foundations of measurement and includes considerations of the responsibilities associated with the use of educational assessments and the rights on people being assessed. These issues are fundamental to educational measurement and woven into the research in ways that are distinct from statistical methods.

The goal of this section is to provide readers with a useful survey of the topics in educational measurement and the statistical methods used in educational research and practice. The topics included are broad but not fully comprehensive. Readers coming to this area for the first time should be able to find an introduction to the field including topics that are the basic foundations

of the field (e.g., reliability or linear regression) and emerging topics (e.g., advanced machine learning or intelligent tutoring). For individual topics, the goal is to give readers a brief introduction that highlights some of the key aspects of the topic. For basic statistical methods, chapters typically include an example to highlight how the methods work in practice. Our goal is that after reading a chapter, users will be familiar with the topic and have enough information to decide if a statistical method might be of use for an application or if a topic is something they should explore further to help them pursue their research interests or solve a problem.

Key Themes and Topics Covered

One of the defining and long-term persistent features of educational practice and research is the interest in the measurement of students' educational knowledge and skills. The goal of education is for students to learn and acquire new knowledge and skills; so measuring the knowledge and skills is clearly important for studying, evaluating, and directing education. Thus, educational measurement is an essential topic to be covered as part of the section on quantitative methods in educational research.

Beyond educational measurement, quantitative methods for education research and practice encompass many topics in multiple fields. We chose to focus on statistical methods because they comprise an essential component of educational research and because there exists a set of statistical methods that are commonly associated with educational applications and truly key for any researcher, student, or practitioner interested in quantitative methods for education. Hence, the topics covered in this section pertain to either educational measurement or statistical methods.

Educational Measurement

The field of educational measurement encompasses theoretical concepts such as the philosophy of measurement and abstract mathematical psychometrics as well as topics related to the practice of developing, administering, and scoring assessments of people's knowledge and skills. Someone coming to the field should have a familiarity with the theoretical foundation of educational measurement and the practice and application of educational assessments. In recent years, the field of assessment has undergone significant changes in response to the widespread introduction of digital assessment and the data that it produces. In this section we attempted to find topics across the spectrum from foundational theory to the most recent applications of digital assessment. Education is a core component of all human societies and educational measurement must support the societal role of education and be responsive to it. Hence, we also include topics to give some sense of how educational measurement fits into the broader social context. We group the chapters into seven broad topic areas roughly ordered from more theoretical topics to more applied topics. The section only covers a portion of all the topics we could cover in educational measurement. They give readers a broad introduction to educational measurement and include topics everyone interested in the areas should be familiar with.

Foundational Concepts

We begin the section with an overall history of the discipline of educational measurement in the chapter titled "Past, Present, and Future of Educational Measurement." This chapter sets the material on educational measurement in its historical context helping readers to understand where practices and the conceptual foundations of educational measurement arose and came to be the standards of the field. It also describes the fields troubling past as part of the eugenics movement and sets the stage for the future looking at coming trends including issues of equity.

The historical perspective is followed with a discussion of the role of standards in the practice of educational measurement in "Educational Testing: A Review of Standards, Guidelines, and Practices." This chapter acknowledges the dual nature of the field of educational measurement as both an academic discipline and a set of methods and practices used in assessment of individuals for consequential decisions for the individual or the systems that educate them.

The first two chapters are meant to ensure readers understand how fundamentally important the ethical responsibility of protecting test takers is to the field of educational measurement. Measurement of cognitive skills at the core of educational measurement is distinct from measuring physical objects which is the heart of physical science. Measurement of cognitive skills is indirect and based on inference. This allows for imprecision and biases. Moreover, educational measurement makes inferences about the abilities and skills of individual people. These inferences can be used for high stakes decisions such as employment or acceptance to higher education. Hence, it is critically important that educational measurement takes steps to protect the individuals being measured and the field has established ethical codes and practices to meet that requirement. The code is most explicitly laid out in the standards discussed in the chapter "Educational Testing: A Review of Standards, Guidelines, and Practices." However, it is also clearly part of the history of educational measurement and woven into the fabric of all the aspects of educational measurement and all the topics and chapters in this section of the Encyclopedia. These first two chapters are an important read for anyone coming to the field to understand the ethical underpinnings of the field.

The remaining three chapters in Foundational Concepts describe the three properties that are the basis for all measurement. Educational measurements must be reliable, support valid inferences, and be fair to the people being measured. Given these are such foundational properties for educational measurement, the chapters "Reliability," "Validity," and "Fairness" provide an introduction to the core concepts, but their authors also acknowledge that even core properties evolve and the chapters provide perspectives on how the concepts are changing and might continue to change in the future.

Modeling Frameworks

The chapters in the section Modeling Frameworks provide an introduction to the basic psychometric models of educational measurement. Psychometric modeling has generally followed two broad paradigms: classical test theory and latent variable/item response theory. Classical test theory is the more traditional approach and focuses on identifying and assessing the errors in test scores. The first two chapters, “Classical Test Theory” and “Generalizability Theory and Applications,” present models from the classical test theory paradigm.

Item response theory (IRT) posits a latent variable or ability and models test takers’ responses as probabilistic functions of their latent variables. The remaining chapters in this section are all from the IRT paradigm. Although models of the form of the IRT models have been around for over 80 years, widespread use of these models for measurement practice is more recent, occurring in the last 30 or so years, substantially after the use of classical test theory. There has been and continues to be very active research into developing new models in the latent variable paradigm.

The chapters in this section survey the diverse models from this paradigm. They start with an introduction to the basic IRT model and then consider adaptations and extensions such as modeling multiple latent variables for each test taker and the adaptation for classifying test takers skills via diagnostic models. The chapters also consider both classical (frequentist) and Bayesian methods for fitting the models and making inferences about test takers. The chapters not only give readers an introduction to models used in practice and research, but they also give readers a sense of how the models have evolved and might be further adapted for additional applications.

Test Development

Whereas Model Frameworks section presents an introduction to the mathematical theory underlying educational measurement, the chapters in the Test Development section turn to the practical side of educational measurement focusing on the design of assessment systems and tests. The chapters in this section are forward looking often focusing on the use of technology in testing and test development and other topics related to recent changes in testing and society such as increased globalization.

A theme to this section is the importance of the design for ensuring that inferences drawn from test scores are valid and supported with strong evidence. This theme runs through the first three chapters, “Principled Assessment Design,” “Evidence-Centered Design,” and “Cognition-Centered Design Principles for Digital Assessment Tasks and Items.”

A second theme is the role of automation and technology in assessments and their development. This theme is related to the broader theme of the impact of the transition to digital assessment and the increasing role of technology in testing. Automation of the development of tests through automated item generation and test assembly is increasing in practice and likely to be more transformational in the future as methods and technology evolve. Hence, these are key chapters for readers who want to see the direction of educational measurement. Adaptive testing is an example of the way digital assessments are changing testing and will continue to do so.

The section ends with another key component for ensuring the validity of inferences: score reporting. Again, digitalization is affecting reporting and offers great opportunities for making scores more informative and maintaining the validity of inferences drawn from the scores. Growing globalization makes translation and adaptation of testing increasingly important. This chapter gives readers a brief introduction to this topic and helps prepare them for educational measurement practices in the future.

Establishing the Quality of Scores

The section on quality control also focuses on the practice of assessment. Chapters in this section cover many practices and methods that are used to ensure test scores are reliable, fair, and support the inferences and decisions made about test takers. The chapters start with the very traditional and universal practices of equating, linking, and scaling of scores and testing for differential item functioning. These are foundational concepts for which anyone interested in educational measurement should be familiar.

All the models presented in Modeling Frameworks make various assumptions about the nature of the data generated by the assessment and its relationship to the attributes of the test takers that are of interest. For those models to provide useful information, the models must fit the data. Consequently, an active field in educational measurement is development of methods for evaluating model fit. Multiple chapters in the section provide readers with an introduction to this important practice and its growing research base.

Respondents’ actions and tendencies when responding to assessments can invalidate inference made from their responses. Methods to detect such behaviors and tendencies are a standard part of practice, and the development of new detection methods is an active area of research. Multiple chapters in this section provide readers with broad introduction to the traditional and emerging research and practices in detecting problem behaviors of test takers. Topics covered include the detection of cheating and aberrant responses, modeling response times, and response styles. Cheating and other forms of aberrant responses pose significant risks to the validity of inferences drawn from test scores because the scores might not reflect the test taker’s ability, knowledge, or skills.

Methods to detect possible problem behaviors or scores also are an active area of research and checks for cheating are commonly part of the practice of assessment. Response times can also provide valuable information about a test taker’s interaction with the assessment. This information can have many purposes, and with the rapid expansion of digital assessments, use of timing data to evaluate test takers or their behaviors has been growing. The chapter “Modeling Response Times” introduces this field of research and practice.

Test takers may have tendencies in their responses to assessment items such as not using extreme responses when responding to Likert items. We provide readers with an introduction to the emerging field of modeling such behaviors in the chapter “Response Style Modeling.”

A final source of potential error considered in the section is the errors introduced by human raters of constructed response items. Readers can find information on the burgeoning field of modeling the tendencies of raters to make systematic errors in the chapter “Rater effects modeling.”

Educational Policy

In addition to assessing individuals, educational measurements are used to evaluate education systems such as schools or school districts or entire countrywide systems. In certain countries, e.g., the United States, the assessments are used to hold educators accountable for student outcomes. More broadly, around the world a goal is to use assessment scores to improve education systems. A major component of educational assessment’s contribution to educational policies is through surveys of the knowledge and skills of student or adult populations in international programs such as the Programme for International Student Assessment (PISA; [OECD, n.d.a](#)), the Programme for the International Assessment of Adult Competencies (PIAAC; [OECD n.d.b](#)), the Trends in International Mathematics and Science Study (TIMSS; [IEA, n.d.](#)), the Progress in International Reading Literacy Study (PIRLS; [IEA, n.d.](#)), or the Programme for the Analysis of Education Systems (PASEC; [The World Bank, n.d.](#)) or programs in individual countries such as the National Assessment of Educational Progress (NAEP; [National Center for Education Statistics, n.d.](#)) in the United States. The programs are described in two chapters. One, “Educational surveys: Conceptual overview,” gives an overview of the goals and objectives of the programs, and the other, “Educational surveys: Methodological foundations,” presents the common test design and statistical modeling approaches used in these surveys. The methods are distinct from most other assessments because the intended inferences for the surveys are about population groups and relationship among variables for populations. They are not intended for inferences about particular individuals, which are the target of other educational measurements.

The remaining chapters in this section relate to practices and models used to support educational policy. Standard settings are used in many contexts where test scores are used to classify test takers by their performance, including licensure. In the policy context in the United States, they are used to set cut scores for classifying students into proficiency categories and this classification is widely used in educational policy. The “Standard Setting” chapter reviews procedures for setting cut scores and considerations in making classifications.

Growth and value-added modeling are used for educational accountability in the United States and other countries. The chapters “Achievement Growth Modeling” and “Value-Added Modeling” provide readers with a general overview of both modeling approaches and discussion of their applications and the concerns about their use for policy decisions. These chapters again echo the importance of issues around the ethical use of educational measurement through their discussion of the potential unintended consequences of using test scores in growth or value-added modeling for educator accountability.

Interdisciplinary Frontiers

The chapters in the section Interdisciplinary Frontiers provide readers with further examples of how digital assessments and computer technology have changed the landscape of educational measurement. These chapters are likely to be important to readers in the coming years as the use of the practices described in the chapters expands and basic understanding of the applications becomes increasingly valuable. The topics covered in the chapters “Automated Scoring of Constructed-Response Items in Educational Assessment,” “The Current Trends and Opportunities for Machine Learning in Learning Analytics,” and “Computer-Based Process Data Analysis” share a common theme of the use of computer algorithms to extract and process data from test takers interactions with digital assessments to yield scores or other measures for individual test takers. Automated scoring uses algorithms to extract information from constructed (e.g., written or spoken) responses. Process data use computer algorithms to extract information from data about students’ interactions with the assessment other than their actual responses such as timing data, changes to responses, or the use of hints or aids that might be provided. Both methods tend to use machine learning ([Hastie et al., 2009](#)) as part of the extraction or synthesis of the data. Analytics uses various computer algorithms, potentially including algorithms used in automated scoring or extracting process data, to provide information to support learning.

The final chapter in this section, “Modeling of Network Structures,” focuses on another area of rapid growth in methodological development and applications: network analysis. Network analysis models connections in data such as modeling social connections, but it is also commonly used in analytics research.

Application Areas

The final section under Educational Measurement offers readers additional insights into educational measurement through a series of measurement applications. The applications include more traditional ones such as the use of educational measurements in certification and licensure, higher education admissions, and classroom assessment. They also include application areas that have evolved and continue to evolve with changes in technology and digital assessments. These include intelligent tutoring, simulation and game-based assessment, conversation-based assessment, and the assessment of collaborative problem-solving. Educational measurement is often associated with the assessment of quantitative and literacy skills or other traditional disciplinary subject matter such as science or history. However, research continues to demonstrate the importance of interpersonal and intrapersonal skills for success in school and work and the assessment of these skills is of increasing interest and seems likely to continue to be so in the future. Hence, we include an introduction to these skills and their assessment in the chapter “Assessment of Interpersonal and

Intrapersonal Skills.” Like the other sections, the applications included in this section provide readers with a grounding in the traditional and foundational aspects of educational measurement as well as an introduction to topics that are likely to be of importance in the future.

Statistical Methods

The chapters in the section Statistical Methods provide readers with an introduction to statistical methods that have wide application for educational research or practice. The chapters are grouped into two sections titled Modeling Frameworks and Foundational Methods. The chapters in Modeling Frameworks present statistical modeling approaches that can be used in data analysis. The chapters in Foundational Methods focus more on foundational concepts such as families of distributions, paradigms for inference (frequentist, Bayesian, or resampling), and the statistical approaches to study design. The chapters describe the models or methods including guidance on how they can be used to support quantitative research. To demonstrate their use, most chapters include an application from the field of education. The treatment of these topics focuses on their application rather than the mathematical foundations. The goal is for readers to have a basic understanding of what the method and models are and some insights into how they might apply them to their own research and applications.

Modeling Frameworks

The models described in the section Modeling Frameworks include classical models that make up the foundation of any applied statistics toolkit. They include analysis of variance, analysis of covariance, linear and nonlinear models, categorical data models, and generalized linear models. In addition to these standard models, there is a chapter on hierarchical linear models which are of great importance to educational research given that data on students are typically hierarchical with students grouped into classrooms and schools and sometimes into groups of schools. There are also chapters on standard multivariate modeling techniques including principal component analysis, exploratory and confirmatory factor analysis, clustering methods, and latent class analysis. Beyond these classic models and approaches there are chapters on structural equation models and growth mixture models. Recent advances in the field are also included in chapters on causal modeling and advanced machine learning.

Foundational Methods

The chapters in Foundational Methods review general statistical principles that are the foundation for the statistical models used in quantitative educational research. These principles include approaches to statistical inference and general theories of estimation. There are introductions to the primary paradigms of inference Bayesian and frequentist approaches. In addition, we include an introduction to resampling methods for inference. Resampling is an approach to conducting inference from the frequentist perspective that relies on fast computing power to provide inferences when traditional methods are difficult to apply. The chapter on estimation covers three methods for parameter estimation: least-squares, maximum likelihood, and Bayesian. These methods are all increasingly widely used and nearly all applications use one of these methods for estimation.

In addition to chapters on the foundations of parameter estimation and inference, Foundational Methods includes chapters covering continuous and discrete distributions and measures of correlation and association. Statistics are key to designing studies, and this section includes three chapters on study design. The first, “Research Study Design” is a general overview of study design including randomized experiments and observational studies. The second chapter on design, “Sampling Designs for Educational Research,” focuses more narrowly on the sampling of study participants and the concepts of survey sampling. The final chapter on design is “Power Analysis.” A critical component of every study or sample design is the determination of the sample size needed to conduct the study to produce precise estimates and meaningful inferences. Power analysis provides information to support the decision on sample size and hence is a critical component of study design. The chapter provides the basic concepts in power analysis but focuses on study designs for hierarchical or nested data (i.e., students in classrooms) because such designs are extremely common for educational studies.

The final chapters in the Foundational Methods section cover the challenge of the analysis of incomplete data, i.e., data with missing values, the graphical displays of data, and meta-analysis. Missing data are a challenge faced by nearly all quantitative studies. The chapter “Missing Data Analysis” provides theoretical basis for conducting analysis with incomplete data and describes common approaches including some more recent advances. The chapter “Displaying Information: From Woolly Mammoths to the Great Migration” describes some general principles and advantages of displaying data graphically and uses multiple examples to demonstrate the power of graphical data displays. The final chapter presents an introduction to meta-analysis which combines data from multiple other studies. Meta-analysis has and continues to play an important role in educational research. This chapter offers a general introduction to the method of meta-analysis and notes some recent advances.

Emerging Issues

New issues emerge constantly in all fields of study including education. The tools of statistical methods and basic educational measurement continue to be applicable to whatever new issues arise. For this reason, this section of the Encyclopedia offers readers introductions to many of the foundational concepts, models, and methods used in quantitative research generally and specifically for educational applications. Although the foundational principles and standard methods remain mostly unchanged and

applicable, statistical methods and models and practices in educational measurement continue to evolve. New models become a standard part of the research landscape as happened with the application of hierarchical linear models in the 1980s and 1990s. Increasing computational power makes the estimation of some models feasible as in the case of the estimation of Bayesian models and multidimensional latent variable models (e.g., multidimensional IRT). There are also innovations and new perspectives such as the use of multiple imputation for incomplete data. However, all these changes build on the fundamental concepts presented in this section.

The foundations of educational measurement also remain stable, but the practices change more rapidly. For example, the conceptualizations of validity evolved substantially from the 1950s to today. Also, there continue to be adaptations and variations to IRT models that work their way into common practice.

One of the main drivers of change to general statistical methods and educational measurement is the continuing growth in computational resources and technology. As noted earlier, this has allowed for new approaches to fitting statistical models, use of more complex models, and expanded the uses of resampling and Bayesian methods for inference. Artificial intelligence and machine learning also continue to evolve with new algorithms, computational methods, and models. These changes are affecting many areas of our lives and they will very likely have notable impact on quantitative educational research. The continuing growth in the use of digital testing and the large volumes of data this can produce provides even more opportunities for AI to affect educational measurement and quantitative research.

Education is deeply embedded into society; so societal changes outside of education per se are likely to affect quantitative methods in education. One example is the growing concerns about equity and justice in the United States and other countries. General concerns and focus on inequity and structural racism in society ignited concerns about the equity and the validity of educational assessments for all test takers, in particular, people of color and other historically disadvantaged groups (Sireci, 2021). These concerns have recently led researchers to suggest the need for participation by individuals from diverse groups in the design and development of assessments so that their perspectives can be considered throughout the process and the results will give all test takers equal opportunity to demonstrate their knowledge, skills, and abilities. There are also calls for changing test items and test designs to be socioculturally responsive and actively acknowledge the inherent biases in nearly all aspects of current educational assessment practices (Randall, 2021). Practices and methods are only catching up to the challenges being identified. It is highly likely that issues around assessment and equity and developing tests that are responsive to sociocultural context will have a substantial impact on educational measurement in the coming years both in practice and theory. In terms of practice, there is a need for more specific guidance on how to create assessments that are socioculturally responsive. There also is likely to be a need for new psychometric models for analyzing data created by such assessments.

As with most scientific fields, the discipline of educational measurement has been—and continues to be—defined by both theory and practice. In what follows, we provide an overview of the past, present, and future of the field. We begin by examining the historical events in the 1800s that led to the development of a coherent mathematical theory of test scores in the first half of the 20th century. We also describe the rise of large-scale testing beginning with the Army Alpha test in 1917 and the administration of IQ tests to millions of school children in the decade that followed. We continue by discussing the current state of educational measurement theory and practice and the ways that both continue to be shaped by cultural context. Finally, we consider directions and developments that are likely to define the future of the field.

The past: the foundations of educational measurement

Systematic attempts to measure educational achievement date back more than 1000 years to the advent of Chinese civil service testing (DuBois, 1970). By the end of the first millennium, this process had developed into something that we would now recognize as standardized testing: tests based on pre-established content administered under controlled conditions with set time limits. In some cases, written responses were even transcribed so that a test taker's calligraphy could not be recognized by the person scoring the response (DuBois, 1970).

Within the western tradition, university testing for ranking and graduation dates back hundreds of years; by the middle of the 18th century, written tests were being used to evaluate and rank Cambridge students seeking to graduate with honors in mathematics (Neale, 1907). The same testing approach soon spread to other subjects and other universities, and by the late 19th century standardized tests were being used in England to select individuals for the Indian civil service. These types of tests were the model that Francis Edgeworth had in mind when he wrote what may be the first paper to develop a framework for understanding the precision of test scores (Edgeworth, 1888).

Given this history, it is impossible to identify a single point that represents the beginning of the field of educational measurement. It is clear, however, that much of what we consider the theoretical underpinnings of educational measurement and a good bit of the practice began in the intellectual climate that existed in late 19th century England (See Table 1 for an overview of the early history of educational measurement.).

Table 1 Major events in educational measurement: 1850 to 1950.

1859	Darwin	Publication of <i>On the Origin of Species</i>
1869	Galton	Publication of <i>Hereditary Genius</i>
1888	Edgeworth	Publication of <i>The Statistics of Examinations</i> (first paper on the precision of test scores)
1889	Galton	Publication of <i>Natural Inheritance</i> and introduction of the correlation coefficient (in a separate paper)
1896	Pearson	Publication of <i>Mathematical Contributions to the Theory of Evolution, III: Regression, Heredity and Panmixia</i> (introduced the product moment correlation coefficient)
1904	Spearman	Publication of <i>The Proof and Measurement of Association between Two Things</i> (introduced formula for true-score correlation)
1905	Binet and Simon	Begin publication of a series of papers on the development of intelligence in children (1905–11)
1909	Galton	Publication of <i>Essays in Eugenics</i> (introduced the science of eugenics)
1910	Spearman and Brown	Publication of <i>Correlation Calculated from Faulty Data and Some Experimental Results in the Correlation of Mental Abilities</i> (introduced the Spearman-Brown formula)
1916	Lippman and Terman	Lippman-Terman Debate published in <i>The New Republic</i>
1924	Kelley	Publication of <i>Note on the Reliability of a Test</i> (Began Kelley's program of research that formalized classical test theory)
1925	Thurstone	Publication of <i>A Method of Scaling Psychological and Educational Tests</i> (presented model for placing items and examinees on a common scale)
1926	College Board	First administration of multiple-choice based SAT
1937	Kuder and Richardson	Publication of <i>The Theory of Estimation of Reliability</i> (introduced the KR-20 and KR-21 measures of reliability)

The London school and the development of classical test theory: Galton, Pearson, Spearman and beyond

In describing the foundation of classical test theory, Gulliksen (1950) stated that, “Nearly all the basic formulas that are particularly useful in test theory are found in Spearman’s early papers”. The theoretical framework that grew out of those formulas remains an essential part of educational measurement. We begin by examining the genesis of Spearman’s work.

The chain of events that led to these formulas can be traced back to November 24th, 1859: the date of the first publication of Charles Darwin’s *On the Origin of Species by Means of Natural Selection*. The direct impact of this text on the biological sciences is obvious, but its indirect impact on the social sciences also was profound; that impact was mediated through Darwin’s first cousin, Sir Francis Galton.

Francis Galton

Galton was the quintessential Victorian polymath. Like Darwin, Galton began his intellectual career studying medicine; also like Darwin, he never completed his medical studies. Galton contributed to numerous fields during his long life: he explored a part of Africa previously unknown to Europeans (Galton, 1853), created some of the first weather maps and discovered the phenomenon known as the anticyclone (Gillham, 2001), and wrote three books on fingerprints which significantly influenced the adoption of the methodology for individual identification (Galton, 1892, 1893, 1895; Gillham, 2001).¹

Of all of Galton’s efforts, those with the most lasting impact were motivated by his reading of Darwin’s *Origin of Species*. As Stigler (1986) commented, “Darwin’s theories opened an intellectual continent” (p. 267) for Galton to explore, and he spent much of the rest of his life mapping that continent. Though heredity played an important role in Darwin’s theory, the mechanisms of genetics and laws of heredity were not known.² Galton’s study of heredity had an important direct impact on what would become the field of genetics: it produced insights into how characteristics are passed from parents to children and launched the biometrics movement (Gillham, 2001). His work also had a critical—if somewhat less direct—impact on the development of educational measurement. Galton’s study of heredity led to the creation of the correlational procedures that Spearman would use as the basis for the formulas referenced by Gulliksen. Galton’s interest in heredity also led him to launch the science of eugenics (Galton, 1909), which gained widespread acceptance and shaped the cultural context in which early mental tests were developed and applied. (The role of eugenics in shaping educational measurement is discussed in more detail in a subsequent section.)

¹He also was responsible for a number of activities that make him seem like a bit of a crank: he created a beauty map of England (Galton, 1908) and produced a data-based argument to evaluate the efficacy of prayer (Galton, 1872).

²Although Mendel’s work was published when Galton began his experiments with pea plants (Mendel, 1866), it remained essentially unknown to the scientific community until late in the century.

Galton's work to understand heredity was both observational and experimental. His first major work on the topic, *Hereditary Genius*, cataloged instances in which individuals who were outstanding in a field (e.g., art, science, jurisprudence) tended to have relatives who were outstanding in the same field (Galton, 1869). Galton viewed this as evidence that psychological characteristics are inherited in the same way that physical characteristics are passed from parents to children.³

Galton also collected data to explore the laws of heredity. Like Mendel, Galton experimented with peas. Unlike Galton's work on hereditary genius, the results from his experiments with peas and the data he began collecting on human inheritance of physical characteristics provided numerical measures that called for mathematical analysis. His efforts to understand the relationships inherent in these data led to two important contributions to the field of statistics: The first was the concept of regression to the mean, and the second was the correlation coefficient (Stigler, 1986). These statistical contributions led to the widespread use of statistical methods in the social sciences and created a theoretical foundation that would be critical for the development of educational measurement.

Galton's work with peas was motivated by a simple question about how it was that if tall parents tended to have tall children and short parents tended to have short children, over time the characteristics of the population remained stable. Lacking data on humans, at Darwin's suggestion he decided to conduct experiments on peas (Galton, 1908). The results of his experiments showed that the characteristics of the next generation of peas regressed to the mean in a manner completely consistent with maintaining stable characteristics in the population (Galton, 1877). This phenomenon subsequently has been observed and described across a wide range of contexts in which probabilistic events play a role.

Twelve years later, Galton's quantitative approach to the study of heredity led to the introduction of the correlation coefficient. In his autobiography, Galton described how his examination of data relating the characteristics of parents and children led to a breakthrough: "At length, one morning, while waiting at a roadside station near Ramsgate for a train, and poring over the diagram in my notebook, it struck me that the lines of equal frequency ran in concentric ellipses" (Galton, 1908). Although Galton had graduated from Cambridge with a degree in mathematics, his mathematical skills were not outstanding. He collaborated with J. Hamilton Dickson to understand the quantitative relationship represented by the concentric ellipses. This collaboration yielded an index of correlation. Galton described his general approach in detail in *Natural Inheritance* (Galton, 1889). Although the focus of his work and that volume was on heredity, he suggested to the reader that understanding the methodology would be of broad value because "It familiarizes us with the measurement of variability, and with the curious laws of chance that apply to a vast diversity of social subjects" (p. 3).

Galton's work directly influenced numerous scientists that advanced the study of educational measurement. The two most critical links in that intellectual chain were Karl Pearson (who extended Galton's work on the correlation coefficient) and Charles Spearman (who applied correlation to the study of intelligence and in the process developed the tools that would become classical test theory).

Pearson and Spearman

Pearson studied mathematics at Cambridge. Unlike Galton, he excelled in those studies, becoming Third Wrangler in his class (indicating third place in the competitive examination for honors in mathematics). He became professor at University College London and later held the Galton Chair of Eugenics. Pearson was an incredibly productive researcher: The annotated bibliography of his works contains 648 entries (Morant and Welch, 1939) including the paper that introduced the chi squared statistic (Pearson, 1900). Although he wrote at least one paper on the statistics of testing (Pearson and Moul, 1927), most of his work focused on applying statistics to heredity and biology more generally.

For the purposes of this discussion, Pearson's most important work related to refining Galton's approach to correlation (Pearson, 1896). Pearson's name remains attached to the product moment correlation coefficient; his 1896 paper introduced that formulation, replacing Galton's method based on median and interquartile range with the more mathematically tractable version—based on means and variances—that we use today. Pearson's contributions created the foundation upon which Spearman would build to create the tools he needed to study intelligence.

Spearman served the British military for 15 years before resigning his commission and moving to Leipzig to study psychology with Wundt (Spearman, 1930). His doctoral work focused on the psychophysics-based measures that were the essence of the Leipzig school of psychology; interestingly, his dissertation *Die Normaltäuschungen in der Lagewahrnehmung*, which focused on spatial localization, seems to have had no impact on science (Tinker, 1932). His first important papers—published before he completed his doctoral work—were based on his work on the nature of intelligence, which was independent of the research going on at Wundt's laboratory. Those papers were *The Proof and Measurement of Association between Two Things* and "General Intelligence" Objectively Determined and Measured, both published in 1904.

In order to understand the nature of intelligence, Spearman examined how different measures of intelligence are related. He came to believe that intelligence was heavily influenced by a general factor. This interest made correlational analysis essential. Spearman was not the first to use correlation to explore this relationship. Clark Wissler's Ph.D. dissertation from Columbia University (Wissler, 1901) preceded Spearman's work and may have been the first published study in psychology to use Pearson's product moment correlation coefficient (Lovie and Lovie, 2010). Spearman's work, however, went beyond previous studies in an important

³There obviously are alternative explanations for Galton's observations. See Clauser (2021) for a discussion.

way: he recognized that to interpret the correlations between measures he needed to account for the impact of measurement error. To do this, he introduced the formula for estimating true score correlation (the correction for attenuation):

$$R_{\infty} = \frac{r_{11}}{\sqrt{r_{11}r_{11}}}$$

In this formula, the true correlation is equal to the observed correlation between the two measures divided by the square root of the product of the reliability of the measures. The formula appeared in *The Proof and Measurement of Association between Two Things* (Spearman, 1904). In that same paper, Spearman criticized Pearson for failing to account for the reliability of the measures in comparing the magnitude of correlations between physical and psychological characteristics.

Spearman's work was immediately attacked by Pearson (1904). Spearman then responded to the critique with *Demonstration of Formulae for True Measurement of Correlation* (Spearman, 1907). Spearman's last important contribution to classical test theory was *Correlation Calculated with Faulty Data* (Spearman, 1910); the paper was yet another defense against Pearson's attacks. More importantly, however, this paper presented what has become known as the Spearman-Brown⁴ formula,

$$R_{KK} = \frac{Kr_{11}}{1+(K-1)r_{11}}.$$

The formula shows the reliability of a test that has been lengthened as a function of the proportion by which it has been lengthened (K) and the reliability of the original test. The Spearman-Brown formula was of general use, but the most important application was for estimating the reliability of a single test based on the correlation between two half tests (such as those comprising only odd and only even items from the original test). The result is not only practical; it did much to define the way reliability would be conceptualized for the next 100 years.

Contributions after Spearman

Spearman created a foundation for test theory. In the years immediately following his contributions, his work was both applied and evaluated. Several authors examined the empirical accuracy of the Spearman-Brown formula by comparing predictions to empirical results (Holzinger and Clayton, 1925; Remmers et al., 1927; Ruch et al., 1926; Wood, 1926). Each of these studies confirmed the predictions based on the Spearman-Brown formula.

As Pearson's attacks on Spearman began to fade from view, the importance of Spearman's approach became more widely recognized and other researchers extended his work to create *classical test theory* as it was presented by Gulliksen (1950) and Lord and Novick (1968). No one played a more instrumental role in this process than Truman Kelley. Where Spearman had developed tools to advance his program of correlational psychology, Kelley was interested in advancing assessment; in this regard he may be the first true psychometrician. In his 1924 and 1925 papers, Kelley set out the building blocks of test theory, showing that if we have two forms of a test such that $x_1 = a + e_1$ and $x_2 = a + e_2$, where x is the observed score, a is the true score, and e is a "chance factor",⁵

$$r_{12} = \frac{\sigma_a^2}{\sigma_x^2}.$$

Using this starting point, he shows the relationship between the reliability of a measure and the correlation between the measure and the related true score:

$$r_{1\infty} = \sqrt{r_{11}}$$

or equivalently,

$$r_{11} = r_{1\infty}^2.$$

The next critical contribution to the development of test theory came in the form of a paper by Kuder and Richardson (1937). At a time when computing was done by hand, with a slide rule, or with a cumbersome mechanical calculator, the paper provided simplified computational procedures for calculating reliability. This was valuable to practitioners, but perhaps more importantly it established the view that from the perspective of test theory, reliability was to be conceptualized as split-half rather than test-retest reliability. Kuder and Richardson begin with the assumption that $a, b, \dots, n$ and $A, B, \dots, N$ are corresponding items in two forms of a test. They state that the tests are equivalent if the items in each pair (a and A , b and B , etc.) are interchangeable (i.e., the items in one form have the same difficulties and inter-item correlations as those in the other form). Based on these assumptions, they present the KR-3:

$$r_{tt} = \frac{\sigma_t^2 - \sum_1^n p_i q_i + \sum_1^n r_{ii} p_i q_i}{\sigma_t^2}.$$

⁴Brown refers to William Brown. He independently developed a proof of the same formula in a paper published immediately following Spearman's in the same journal (Brown, 1910). Interestingly, Brown was a follower of Pearson and much of his dissertation—on which this article was based—recapitulated Pearson's previous attacks on Spearman.

⁵The original equation given by Kelley did not include a subscript for the variance in the denominator. The subscript has been added because this form is likely to be more familiar to contemporary readers.

In this equation, r_{tt} is the reliability of interest, σ_t^2 is the variance of the test, p is the difficulty for a specific item, and q is $1-p$. Seventeen equations later they present the KR-20, derived from KR-3 with the assumption that all inter-correlations are equal:

$$r_{tt} = \frac{n}{n-1} \cdot \frac{\sigma_t^2 - npq}{\sigma_t^2}.$$

Fourteen years later, Cronbach's paper on coefficient alpha extended this work and represents a kind of capstone on the development of classical test theory (Cronbach, 1951). In that paper, Cronbach showed that alpha represents the mean of all possible split-half coefficients and that it is also "the value expected when two *random* samples of items from a pool like those in the given test are correlated" (p. 331). As Cronbach pointed out, KR-20 is a special case of alpha that applies to tests comprising dichotomously scored items.

From what we have described in the previous paragraphs it should be clear that Spearman's focus on correlational analysis and the introduction of the Spearman-Brown formula provide the foundation on which the theoretical basis for educational measurement was built. The introduction of the Spearman-Brown formula represented the first important step toward conceptualizing reliability as a statistical property of the test (although it is not clear that Spearman recognized that fact). Developments over the next half century were dependent on the way of thinking about test scores that Spearman introduced. During the 50 years over which classical test theory developed, the practice of testing also evolved. Though Galton, Pearson, and Spearman influenced that development as well, their influence was less direct. We discuss the evolution of testing practice in the next section.

Intelligence testing and the eugenics movement

Alfred Binet

During the same time period in which Spearman was writing the papers that would spur the development of classical test theory, Alfred Binet was in France doing research that would shape intelligence testing across the globe for much of the 20th century. Binet's career was eclectic if not totally disjointed. In 1882 he met Jean Martin Charcot and Charles Fere and began spending much of his time in Charcot's laboratory observing and experimenting with the effects of hypnosis on hysterics (Binet and Fere, 1887). Binet's doctoral dissertation was entitled, *A Contribution to the Study of the Subintestinal Nervous System of Insects* (Wolf, 1973). By 1905, Binet had turned his attention to education—specifically to the identification of school children who would benefit from "special" educational programs. As Binet and Simon (1916) described the motivation for their work on intelligence tests:

In October 1904 the Minister of Public Instruction named a commission which was charged with the study of measures to be taken for insuring the benefits of instruction to defective children. ... They decided that no child suspected of retardation should be eliminated from the ordinary school and admitted to a special class, without being subjected to a pedagogical and medical examination from which it could be certified that because of the state of his intelligence, he was unable to profit, in an average measure, from the instruction given in the ordinary schools (p. 9).

They go on to say that such decisions about placement,

... have at all times too much the nature of the arbitrary, of caprice, of indifference. Such a condition is quite unfortunate because the interests of the child demand a more careful method. To be a member of a special class can never be a mark of distinction, and such as do not merit it, must be spared the record (pp. 9–10).

This work resulted in a series of papers that were published between 1905 and 1911; the papers were subsequently translated and published in the United States in Binet and Simon (1916). In the first paper, Binet and Simon discuss the limitations of the then-current approaches to diagnosis, arguing that (a) approaches based on the physical cause of the disability provide no insight into the extent of the intellectual deficit (e.g., *epileptic idiocy*) and (b) approaches that provide diagnostic criteria based on observable manifestations of intelligence have been too vague to be useful. For example, one diagnostic framework stated that "in profound idiocy *the attention is fugitive*," while in imbecility, *the attention is fleeting*" (p. 23).

Binet and Simon (1916) then present procedures for carrying out 30 tests under standardized conditions. The tests were designed to discriminate between different levels of development. At the simple end of the continuum, the experimenter is instructed to move a lit match across the subject's field of vision and record whether he or she follows it visually. The most sophisticated test requires the subject to define abstract terms: e.g. "What difference is there between weariness and sadness?"

With respect to contributions to educational measurement, Binet's work may be viewed as contributing more to practice than to theory, but in developing the tests he made important methodological and conceptual breakthroughs. The first of these breakthroughs relates to the empirical evaluation of tests (items) for inclusion in the scale. Binet and Simon tried out numerous tests and retained those that discriminated between children of different ages. There does not appear to be evidence that they actually plotted what we might now call *item characteristic curves* to evaluate tests for inclusion, but several of the tables in their paper on

application of these new methods present scores as a function of age and could not be more informative if they were converted to graphic form (Binet and Simon, 1916). The second conceptual contribution that Binet and Simon made was the idea of a norm-referenced interpretation of scores.

The Army Alpha test

As noted previously, Binet and Simon created the prototype for what we know as intelligence tests. Like Spearman's work, which ultimately was advanced by Truman Kelley and numerous other psychologists and statisticians, Binet's work became influential because it was advanced by two Americans psychologists: Henry Goddard and Lewis Terman. Goddard had been invited to open a research center at the New Jersey School for Feeble-minded Boys and Girls, in Vineland. Goddard's efforts to evaluate the children at the school left him in search of improved means of assessing developmental status. During a tour of Europe in 1908 he encountered Binet's work and immediately recognized that it would provide a framework for the improved assessment he was seeking (Zenderland, 1998). Terman was researching intelligence in California at the same time; he also recognized the importance of Binet's approach.

When the United States entered the First World War, both Goddard and Terman were invited to be part of a group convened by Robert Yerkes—the president of the American Psychological Association—to explore how psychology could contribute to the war effort. The group met at Vineland and created the basis for the Army Alpha test. The intention was to create an intelligence test that could be used to make placement decisions for the thousands of recruits who would support the war effort (Sokal, 1990). The focus of their effort began with a variation on the model created by Binet. The group quickly realized that for large-scale testing of the sort that they were proposing, an individually administered test like Binet's would not be feasible. Terman had brought a copy of an intelligence test appropriate for group administration to the Vineland meeting.⁶ This test, which relied heavily on a format we would come to know as multiple-choice questions, became the prototype for the Army Alpha. The format allowed for efficient scoring of the test by clerical staff, and by the time the war ended in November 1918, more than 1,700,000 men had been examined (Yoakum and Yerkes, 1920). Although there is some question as to whether the scores were widely used to make decisions about the recruits, there is no question that the test was instrumental in launching large-scale intelligence testing in the United States; it also was a critical step in the rise of the multiple-choice item format.

The eugenics movement

As we mentioned, in addition to introducing the analytic procedures that would be critical to the development of test theory, Galton was a founder of the eugenics movement. The movement became widely popular in England and the United States and was closely tied to intelligence testing. In Galton's writing, the focus often was on approaches for encouraging eugenically superior individuals to have more children (Galton, 1909; Gillham, 2001). Later eugenicists promoted more extreme measures, including preventing those viewed as inferior from having children and preventing members of specific ethnic groups from entering the country. In 1912 Spearman cowrote, "One can conceive the establishment of a minimum index (of general intelligence) to qualify for parliamentary vote, and above all, for the right to have offspring" (Hart and Spearman, 1912, p. 79). After Galton's death, Pearson held the Galton Chair in Eugenics at University College London, and in a speech given at his retirement in 1934 he praised Reichskanzler Hitler's "vast experiment" "to regenerate the German people" (Pearson, 1934, p. 23).⁷

Goddard also explicitly promoted a eugenics agenda. His book *The Kallikak Family* (Goddard, 1912) was designed to show the harm to society that resulted from allowing eugenically inferior individuals to breed. (Kallikak was a pseudonym for a family that Goddard studied; Deborah Kallikak lived at Vineland). The book was a kind of mirror image of Galton's *Hereditary Genius*; instead of tracing recurrent instances of genius within the same family, Goddard traced instances of mental deficiency within a single family.

Before World War II, there can be little doubt that educational measurement and eugenics were closely tied. Intelligence testing served this connection well. At the same time, it should be remembered that during this period the eugenics movement was mainstream and respected. This changed dramatically after the atrocities of the German eugenics project became widely known.

The Stanford-Binet and the rise of the anti-testing movement

In 1916, Terman published his revision of Binet's scale. In 1918, this was followed by the publication of group tests; within 30 months, approximately four million children were tested (Cronbach, 1975). Although intelligence testing and eugenics were mainstream in the 1920s, they were far from universally accepted. In 1922, Walter Lippmann—author and cofounder of the *New Republic*—wrote a six-part attack on intelligence testing and in so doing launched the anti-testing movement that has continued in one form or another for a century. Much of the article was specifically targeted at Terman. Although Lippmann conceded that standardized testing may be fairer and more accurate than the subjective system of grading prevailing in public schools at the time, he raised concerns about the potential of the tests to stigmatize children. He also expressed concern that rather than motivating remediation, low scores may provide justification for failing to provide the resources needed for education. He then moved on to argue against the conclusion that intelligence—as measured by these tests—is inherited and largely unchanged over time. Lippmann's presentation and Terman's response are heavily dosed with sarcasm, but the main points are not so far removed

⁶The test had been developed by his graduate student, Arthur Otis.

⁷This statement clearly reflects Pearson's enthusiasm for eugenics. It should be noted, however, that it was made years before Kristallnacht and a decade before the atrocities of the Holocaust were widely known.

from the essence of the debate that followed the 1969 *Harvard Educational Review* publication of Jensen's "How Much Can We Boost IQ and Achievement?" and Herrnstein and Murray's 1994 publication of *The Bell Curve*. Jensen (1969) and Herrnstein and Murray (1994) both entertain the idea that group differences in scores on intelligence tests are the result of genetic differences. These views led to backlash and accusations—from both within and outside of the academic community—that the authors were racist; the publications also fanned the flames of the anti-testing movement.

The previous pages describe how test theory and testing programs developed in Europe and the United States over the course of the 19th and 20th centuries. We now turn our focus to the measurement theories and applications that define educational measurement in the beginning of the 21st century.

The present: development of current practice in educational measurement

In this section, we examine the issues in theory and practice that define contemporary educational measurement. From the theoretical perspective we consider item response theory (IRT), generalizability theory (g-theory), and the development of a coherent theory of test validity. Practical considerations include a broadening of testing applications and widespread adoption of computer technology for test administration (See Table 2 for an overview of the major events of this period.).

Modern test theory

By the 1950s, classical test theory provided a well-developed framework for evaluating test scores. The value of the theoretical framework was broadly understood; the limitations of the model also were apparent. The framework Spearman had introduced was well suited to the study of correlational psychology; it was less well suited to the understanding, development, administration, and improvement of tests. Classical test statistics are a function of the set of items administered as well as the sample of test takers responding to those items. The classical model for reliability also assumes a true score and an undifferentiated source of error. This model is less useful for understanding the performance of assessments with more complex designs (e.g., tests where error is introduced by the selection of items and the raters who score those items). Similarly, early conceptualizations of validity tended to focus on correlation with criterion measures (Kane and Bridgeman, 2021; Thurstone, 1931); this narrow focus neglected a range of issues that now are recognized as important in contemporary validity theory.

Item response theory

IRT has become all but ubiquitous within large-scale educational assessment. As noted above, classical test theory is limited in that the resulting statistics are a function of the set of items that were administered and the sample of test takers responding to those items. For example, the difficulty of an item is defined as the proportion of test takers in the sample responding correctly to that item; if the item were administered to a different (i.e., more or less proficient) sample of test takers, the item difficulty would change.

Table 2 Major events in educational measurement: 1950 to the present.

1950	Gulliksen	Publication of <i>Theory of Mental Tests</i> (the first comprehensive monograph on test theory)
1951	Cronbach	Publication of <i>Coefficient Alpha and the Internal Structure of Tests</i>
1952	Lord	Publication of <i>A Theory of Test Scores</i> (introduces framework for item response theory)
1960	Rasch	Publication of <i>Probabilistic Models for Some Intelligence and Attainment Tests</i> (introduces Rasch model)
1968	Lord and Novick	Publication of <i>Statistical Theories of Mental Test Scores</i> (makes Birnbaum's work on logistic IRT models widely available)
1969	Jensen	Publication of <i>How Much Can We Boost IQ and Scholastic Achievement?</i> (raises questions about the connection between intelligence and race)
1969	NAEP	First administration of the National Assessment of Educational Progress
1971	Cronbach	Publication of <i>Test Validation</i> in 2nd edition of <i>Educational Measurement</i> (incorporates construct validity into the structure of validity theory)
1972	Cronbach et al.	Publication of <i>The Dependability of Behavioral Measurements: Theory of Generalizability for Scores and Profiles</i> (introduces generalizability theory)
1989	Messick	Publication of <i>Validity</i> in 3rd edition of <i>Educational Measurement</i> (highlights construct validity and the role of consequences in validity)
1995	TIMSS	First administration of the Trends in International Mathematics and Science Study
2000	PISA	First administration of the Program for International Student Assessment
2001	PIRLS	First administration of the Progress in International Reading Literacy Study
2006	Kane	Publication of <i>Validation</i> in 4th edition of <i>Educational Measurement</i> (presents validation as a structured argument)

IRT represents an explicit effort to produce estimates of item and test-taker characteristics (parameters) that are invariant across samples. The common way of formulating the resulting relationships is through an equation such as:

$$P(\theta) = \frac{1}{1 + e^{-a(\theta-b)}},$$

which shows that the probability of a test taker with a specific proficiency level θ responding correctly to a(n) (dichotomously scored) item is a function of the difference between test taker proficiency, item difficulty b , and item discrimination a .⁸ Creating estimates of item and test-taker parameters that are invariant across samples clearly has theoretical appeal; doing so also has numerous practical advantages. These models created new and more flexible ways to equate test forms. They also created a framework for targeting test items to the proficiency level of a specific test taker—opening the way for computer-adaptive testing—and targeting items to a cut score to minimize classification error. Use of IRT for optimizing test development, equating, and administration is now commonplace, but development of practical applications took time, as estimation procedures and computer technology needed to catch up with the underlying mathematical theories.

Development of item response theory in the United States

In science, it is occasionally the case that researchers working independently arrive at similar breakthroughs at nearly the same time.⁹ The development of IRT—the origins of which occurred primarily in the United States and Denmark with contributions from researchers in other countries (in particular, the Netherlands)—is such a situation. Although the birth of the theory tends to be associated with the publication of Frederic Lord's (1952) *A Theory of Test Scores*, several researchers had contributed important ideas during previous decades. For example, Thurstone (1925) demonstrated how items and people could be scaled together; during the Second World War, Lazarsfeld (1950) did important work on scaling latent traits such as the proficiency that would be integral to IRT. Despite these other contributions, it is clear that Lord's monograph was the first to lay out the basics of the theory as we know it today. Publication of the monograph was soon followed by a paper published in *Psychometrika* in which Lord (1953) presented the two-parameter normal-ogive model:

$$P(\theta) = \int_{-\infty}^{a(\theta-b)} \frac{1}{\sqrt{2\pi}} e^{-.5z^2} dz.$$

This equation defined the theoretical basis for IRT, but the mathematical intractability of the formulation made actual use of the model all but impossible. It took nearly 15 years and the publication of Birnbaum's work in Lord and Novick's (1968) *Statistical Theories of Mental Test Scores* for the normal-ogive model to be replaced with the logistic form that we use today.

Rasch Measurement

This two-decade-long effort by Lord to create a practically useful IRT model was paralleled by Georg Rasch in Denmark. Rasch was a trained statistician who had studied with R. A. Fisher; he began working on educational data in the 1950s. As he later described his work, "When I got the data I made the guess that it might be a good idea to try the multiplicative Poisson model. It turned out to fit the data quite well." (Rasch, 1980, p. xiii). As this quotation suggests, Rasch started by fitting a model to the data. Over time, however, Rasch came to stress the importance of the data fitting the model rather than the model fitting the data.

What has become known as *Rasch measurement* has focused on the importance of two characteristics of measurement procedures. The first is that the raw score is a *sufficient statistic* for the modeled score. Given that sufficiency is a concept central to Fisher's work, it is not surprising that Rasch recognized its importance. The other characteristic is what Rasch referred to as *specific objectivity*. This refers to the fact that measurement is invariant across samples. Because of the emphasis Rasch placed on the data fitting the model and the need for sufficient statistics, the basic Rasch model is equivalent to Birnbaum's logistic model with a single parameter representing item difficulty—it explicitly excludes a discrimination parameter.

Extensions and Applications

The models developed in the US and Denmark were rapidly extended by other researchers. Within the Rasch framework, Andrich (1978) and Masters (1982) developed models for items that are scored polytomously. Samejima (1969, 1972) and Bock (1972) provided related models that can be viewed as extensions of Lord and Birnbaum's work. van der Linden and Hambleton's (1997) *Handbook of Modern Item Response Theory* presented twenty-seven models - including polytomous and multidimensional extensions of the logistic models as well as models incorporating response time.

Although the development of these models has been important, the direct application of IRT to testing problems has been even more critical to the practice of educational measurement. IRT created a practical approach to constructing large item banks that can be used to build equivalent test forms (through an approach referred to as pre-equating) and to support

⁸When applied to multiple-choice questions, the model is also commonly modified to reflect the fact that even test takers with very low proficiency will have a non-zero chance of selecting the correct answer.

⁹Well-known examples of this phenomenon include the development of the theory of evolution through natural selection by both Darwin and Wallace, the creation of calculus by Newton and Leibniz, and development of the Spearman-Brown formula.

computer-adaptive testing (sometimes referred to as CAT). The mathematical theories and conceptual applications largely were defined by the time Lord published *Applications of Item Response Theory to Practical Testing Problems* (Lord, 1980), but practice lagged because estimation procedures and robust software for implementing these models were unavailable. This would change in the 1990s.

Generalizability theory

The development of IRT was motivated by the desire to produce test-taker and item parameter estimates that are invariant across samples. As the theory developed, it also provided a convenient model-based approach to estimating conditional standard errors for proficiency estimates. IRT has, however, remained linked to the basic classical test theory model in that it conceptualizes error as being undifferentiated. In contexts in which tests are comprised of a random sample of items that can be mechanically scored as correct or incorrect, this mode is adequate. For conditions in which tasks are scored by human judges or items are sampled from predefined content categories, however, this model likely will be inadequate (and in some cases, grossly inadequate). Generalizability theory is an effort to model the different facets of the testing process so that their contributions to measurement error can be appropriately represented in determining the precision of test scores and in planning administration procedures.

The concepts formalized as generalizability theory by Cronbach et al. (1972) were described first by Francis Edgeworth (1888). The basic approach is based on analysis of variance procedures which allow for isolating the different components (or facets) of the measurement procedure that contribute to score variance—particularly those facets that contribute to measurement error.¹⁰ Edgeworth conceptualized tests as being constructed through random sampling (the central assumption of generalizability theory). He conceptualized the error impacting a test score as comprising multiple facets including what we now call task effects, rater effects, rater-by-task interactions, and person-by-task interactions. He noted both that the total error would equal the square root of the sum of the squared effects and that the impact of any effect will be reduced by the square root of the number of observations.

Although Edgeworth outlined much of what we would currently describe as generalizability theory, his papers appear to have been forgotten by later researchers. Some researchers (e.g., Burt, 1936, 1955) returned to this problem earlier in the 20th century, but the major contribution came when Cronbach et al. (1972) published their monograph. This provided what the authors described as a *liberalization of classical test theory*, and their approach has defined the state of the art for evaluating the precision of test scores for the last half century. Despite the obvious theoretical improvement that generalizability theory offered, classical test theory approaches—such as coefficient alpha—have remained in common use; in his final published paper, Cronbach (2004) continued to argue that correlational methods of estimating reliability should be replaced with analysis-of-variance-based procedures. He believed that the earlier approaches had served correlational psychology well, but that they were inadequate for evaluating the kind of testing that had become common by the end of the 20th century.

Validity theory

Many of the theoretical developments that define educational measurement are based explicitly on statistical models. Interestingly, perhaps the most important theory—*validity theory*—is more philosophical, or conceptual. As with the other theoretical frameworks that support educational measurement, this one has developed over the course of the last century. There is a sense in which the concept of validity has been stable over time, consistently referring to the extent that a test score is useful for its intended purpose.¹¹ What has changed is the range of intended purposes that have been considered and the extent to which validity has gone from an *ad hoc* evaluation to a systematic and principled framework.

In the period following World War II, considerable attention was being given to tests that would predict future performance. This included selection and placement tests in industrial and educational settings. Because the purpose of these tests was to predict a criterion, validity was frequently expressed as a correlation between the test score and the criterion. Thurstone (1931) defined validity exclusively within this framework, and Cureton's article on validity (1951) in the first edition of *Educational Measurement* (Lindquist, 1951) focused substantially on this aspect of validity. By the time the second edition of *Educational Measurement* was published (Thorndike, 1971), the conceptualization of validity had expanded substantially. It was recognized that different approaches to validity may be necessary for different types of tests: Correlations may be appropriate for tests that are used to make predictions, and approaches that evaluate the content of the test may be needed for achievement tests. In the case of tests for which there is no readily available criterion and no definitive content (such as psychological tests), Cronbach (1971) recommended a construct validity framework. Unlike predictive validity and content validity, which focus on a single outcome, construct validity requires a program of research to evaluate whether the test scores behave in a manner that is consistent with the research and theory related to the construct. Cronbach's (1971) presentation of validity was perhaps most influential in establishing that test validity would require an ongoing program of research regardless of the purpose of the test.

By the publication of the third edition of *Educational Measurement* (Linn, 1989), construct validity had become an organizing principle for validity theory. In addition to elevating the importance of construct validity, Messick (1989) gave considerable

¹⁰Edgeworth (1885) published a paper on analysis of variance decades before Fisher's work (Fisher, 1925) made the methodology common practice.

¹¹Kelley (1927) defined validity as the extent to which a test "really measures what it purports to measure".

attention to the role of consequences in validity. Incorporating consequences into the conceptualization of test validity consciously extends the scope beyond an empirical verification of the usefulness of test scores and explicitly introduces value judgments into the process.

The 2006 edition of *Educational Measurement* (Brennan, 2006) again expanded the view of validity. Kane's (2006) presentation acknowledges the importance of the types of validity evidence discussed in the three earlier editions of *Educational Measurement* and reconceptualizes that evidence as part of a structured argument that supports the interpretations and uses of test scores. This argument-based approach emphasizes that the overall validity argument is only as strong as its weakest part. This approach is consistent with the views of Cronbach and Messick that the process of test validation requires a program of research. It also serves to focus that research on the aspects of the argument which might be most dubious.

Testing practice

Educational tests have become ubiquitous in the modern world, and much of this testing can be seen as a natural evolution from the intelligence and achievement tests that were in wide use in the United States by the middle of the 20th century. Although standardized tests are used in most, if not all, countries, the use of these tests varies across countries.

High-school graduation tests and tests for admission to colleges and universities are common, although the specifics vary by country. In China, the National College Entrance Examination is taken by approximately 10,000,000 students each year. This test determines eligibility for post-secondary education, and because of the impact of the results on later career options, many students spend years actively preparing for it (Larmer, 2014). In Finland, the Matriculation Examination is administered at the end of high school; it acts both as a graduation examination and a requirement for candidates who want to continue their studies at university. In England, students typically take numerous standardized tests (as many as 20) during the final years in high school to earn their general certificate of secondary education and to complete their A levels (which are required for university admissions). In the United States, the two major college entrance examinations—SAT and ACT—are taken by roughly 4,000,000 students each year. The SAT and ACT have been particularly targeted by the anti-testing movement during recent years, and some colleges and universities are no longer requiring test scores as part of the application process.

In addition to high school graduation and college entrance examinations, many countries administer achievement tests. Both the use and purpose of these tests vary across countries and across jurisdictions within countries. Finnish children are unlikely to take this sort of standardized test except in the form of the Matriculation Examination mentioned in the previous paragraph. Germany administers standardized tests in grades 3 and 8 to support improvements in educational practice. The United States makes substantially greater use of standardized achievement tests (although the specifics vary from state to state). Among the first large-scale achievement tests in the United States was *The Iowa Test of Basic Skills* (ITBS). It was introduced in Iowa in 1935 and was quickly adopted by states across the country (Briggs, 2021). Though the initial focus of this and other large-scale achievement tests was on evaluating individual students, that focus has shifted over time. School-level achievement testing continues in widespread use; for example, some states require passing a standardized achievement test for high school graduation. Beyond this, in a controversial and much debated practice, achievement tests are being used to evaluate the performance of teachers. These tests also are used to evaluate schools and school systems.¹²

The most dramatic aspect of the evolution of achievement tests is reflected in national examinations such as the *National Assessment of Educational Progress* (NAEP) in the US and international examinations such as the *Trends in International Mathematics and Science Study* (TIMSS), *Progress in International Reading Literacy Study* (PIRLS), and *Program for International Student Assessment* (PISA). These tests often are based on complex statistical and psychometric models that use sophisticated sampling procedures to support aggregate proficiency estimates without supporting estimates at the level of individual test takers. The results allow for tracking of how states/provinces or countries are performing.

In addition to the ever-broadening applications of testing, another defining feature of current practice is the use of computers in assessment and the potential offered by use of this technology. From a content perspective, paper-and-pencil administration is perfectly acceptable if test material is limited to text and simple graphics; for more complex content, computerization has opened the way for high-quality and low-cost use of color pictures, has greatly simplified the use of audio and video as part of the stimulus material, and makes interactive tasks and simulations possible. In addition to broadening the range of materials that can be presented, computerization also has made a range of approaches to test administration possible: Computer-adaptive testing—in which test items are targeted at the estimated proficiency level of the test taker—has become common, and linear-on-the-fly testing (LOFT)—in which item exposure is controlled by constructing a potentially unique test form for each test taker—is well established. Computerization also has facilitated automated scoring of constructed responses (including essay and short answer questions) and complex performance tasks such as design problems for architects (Braun et al., 2006) and patient management simulations for physicians (Margolis and Clauser, 2020).

In addition to the benefits associated with administration and scoring, computerization has created previously unavailable sources of data about how test takers respond to test items. These data have the potential to substantially improve testing.

¹²Interestingly, evaluation of public schools in Boston was the motivation behind the introduction of some of the first standardized written examinations used in American schools: those introduced by Horace Mann in 1845.

Information on how test takers change answers is now routinely collected as is information about how much time test takers use and how they distribute available testing time across test items. Data of this sort can be useful in evaluating the validity of the intended interpretations and uses of test scores as well as for improving test materials and administration procedures (Margolis and Feinberg, 2020).

The future of educational measurement

Although it is impossible to know the future of educational measurement, a number of current trends are almost certain to shape the future of the field. In the following paragraphs, we describe four of these trends.

Increased use of computational power

Computational power has defined practice in educational measurement for generations. Spearman and Pearson introduced formulas for approximating the correlation coefficient with less computational effort, and the culmination of Kuder and Richardson's landmark paper was the KR-21, which allowed practitioners to calculate reliability based on statistics that were likely to be readily available and so save computational effort. Similarly, widespread use of many IRT applications had to wait for computational technology to catch up with theory (see Luecht and Hambleton, 2021). As practice historically was limited by computational power, more recently it has been enabled by that power. Artificial intelligence, machine learning, and computational linguistics (the application of computer science to the analysis of written and spoken language) already have made an impact on educational measurement, and automated scoring procedures that use these technologies for essays and other constructed responses have been studied for more than a half century (Page, 1967) and used operationally for decades (Margolis and Clauser, 2020). These technologies are likely to become more prevalent in the future, and they have the potential to support automated assessment of both written and spoken responses. Systems driven by artificial intelligence will not only tutor students to improve their writing and math skills; they will allow medical students to practice interviewing patients to improve their clinical decision making and allow for both teaching and assessment of a wide range of similarly sophisticated skills in other disciplines.

The science of test development

For as long as test questions have existed, test developers have engaged in the art of item writing. In recent years, test development efforts have slowly shifted away from the artistic toward the scientific, adopting principled approaches to test development (e.g., Ferrara et al., 2017). *Principled design* refers to constructing assessments in a way that ensures that the interpretations made based on the test scores are aligned with and supported by the evidence from the assessment; it includes approaches such as evidence-centered design (Mislevy et al., 2006), assessment engineering (understanding the characteristics of items that impact item performance; Luecht, 2012), and efforts to generate items using computer technology (e.g., automated item generation, or AIG). Although evidence-centered design has been well delineated, assessment engineering and computer-generation of test items represent technologies that are still in the early stages of development. It is likely that this work will help to define the next generation of educational assessments and that computational linguistics and machine learning will support both the development and operationalization of these efforts. These areas of research are critical because the field of educational measurement can never advance beyond the quality of the test material used in that measurement.

Process data

Closely associated with a more scientific approach to test development is the use of a wide range of data to evaluate how test takers respond to test items. These data often are referred to as *process data* or *meta data*. In some cases, process data can be collected seamlessly and effortlessly when the test is delivered via computer. For example, commonly captured process data include the amount of time test takers spend on each item—both before and after recording an answer—and how this timing information relates to the probability that an item is answered correctly. This type of timing data has been useful for many purposes, such as evaluating whether an assessment is speeded, determining a test taker's level of engagement, and even identifying test takers who may have had prior access to the test material (Margolis and Feinberg, 2020). Another type of process data can be collected with the use of eye-tracking technology, which provides even more specific information about how test takers read, process, and respond to items (Oranje et al., 2017). It is a near certainty that these types of data will be used more widely in the future to provide test developers with insight into the cognitive processes involved with responding to test items. As more use is made of process data, test developers will better understand *how* examinees respond to test items, and educational measurement is likely to become more closely linked to cognitive psychology.

Fairness and consequences

The role of *consequences* and the issue of fairness within the framework of test validity has received considerable attention during the last three decades. Issues that may limit opportunities for already disadvantaged minorities—such as score differences across racial or socioeconomic groups—have been a particular focus of the anti-testing movement. The historical association of intelligence testing with the eugenics movement makes the issue of fairness even more critical. Messick (1989) often is viewed as the major driver for the inclusion of consequences in the understanding of validity, but a careful reading suggests that Cronbach (1971, 1988) and Kane (2013) are equally strong advocates for the importance of consequential validity. As the centrality of consequential validity becomes more widely recognized, issues of fairness in testing will have a greater role in the future of educational measurement (Dorans and Cook, 2016).

Conclusion

We conclude with two points. First, though we acknowledge that predictions are risky, it nevertheless seems a certainty that the basic methodologies that have shaped the past and present of educational measurement—classical test theory, IRT, generalizability theory, and validity theory—will remain an essential part of the future of the field. The second point is that we have provided a perspective on educational measurement that is far from exhaustive. We have emphasized the theoretical advances that make educational measurement a scientific discipline, and in so doing we have neglected large domains—such as day-to-day classroom assessment—and many essential aspects of test administration—such as equating and standard setting—that continue to be the focus of careful study. Although the picture we have painted is unavoidably incomplete, we hope that what is clear are the ways in which the past, present, and future of educational measurement are connected through the theories and practice that have created and sustained this field.

Introduction

Given the central role that testing plays in education, it is important to understand the applicable professional standards that guide responsible and ethical practice. Testing is a broad term and is used to describe many formal and informal practices in service to various purposes and uses, such as informing classroom instruction or as a factor in college admissions. The focus of this work is primarily restricted to large-scale, often standardized achievement tests, especially those used for consequential purposes, such as tests used to inform school accountability. This limited focus is not meant to diminish the full depth and breadth of testing in particular or assessment more broadly. Rather, it is a recognition that the literature prominently emphasizes these applications, which is understandable given that more consequential use demands more attention to standards and ethics.

This article begins with a review of the various sources for professional guidelines and standards, starting with early attempts before exploring more recent initiatives. This section attempts to address both the origins of professional standards and some of the mechanisms that influence practice. Next, the principles or core areas addressed by contemporary standards are explored, including foundations, operations, and applications. The final section addresses issues and future directions, focusing on both critiques of current practice and ideas to promote improvement.

Sources

Early attempts

Initial attempts to establish and document standards and practices for large scale testing in education can be traced to the early 20th century. As described in [Madaus \(2001\)](#) early efforts are associated with Giles Ruch followed by Oscar Buros. In 1925 Giles Ruch lamented the lack of information to guide selection and use of tests and he called for a set of “working criteria for test construction” to be established as well as the adoption of “some fairly uniform practices in reporting on tests” (p. 349). In the 1920s and 1930s Ruch produced numerous publications proposing various technical standards for testing and advocated for a “consumers’ research bureau” on tests ([Madaus, 2001](#)).

A more widely-known and lasting attempt was initiated by Oscar K. Buros which ultimately led to the *Mental Measurement Yearbook* (MMY) starting in 1938. This enterprise grew into what is now the Buros Center for Testing, which to date has produced twenty-one editions of the MMY in addition to the Tests in Print series ([Buros Center for Testing, 2021](#)). From the start, Buros’ objective was to promote improved standards for practice through transparency. He writes in the first edition, “Up to the present time, test authors and publishers have been able to place on the market inadequately validated tests without fear of criticism. Test users have every right to demand that test authors and publishers present full particulars concerning the methods used in constructing and validating the tests” ([Buros, 1938](#), pp. xiii–xiv).

In subsequent years, the MMY served as a form of de facto peer review for test publishers. The process, as described in [Carlson and Geisinger \(2012\)](#), relies on the selection of independent and expert reviewers who examine documentation focused on the development process and evidence in support of reliability and validity with respect to the instrument’s stated uses.

The first initiative to develop standards that had the backing of an influential professional association occurred in 1954. In this year the American Psychological Association (APA) published *Technical Recommendations for Psychological Tests and Diagnostic Techniques*. This was followed quickly by a joint effort of the American Educational Research Association (AERA) and the National

Council on Measurement Used in Education (NCMUE), who produced *Technical Recommendations for Achievement Tests*, published by the National Education Association (NEA) in 1955. Similar to the initiatives that preceded it, these early statements continued to focus on the development process and emphasized the type of information that should be made available for inspection by test users (Plake and Wise, 2014).

Contemporary sources

Academic and professional organizations

Academic and professional organizations have historically made the most prominent contributions to standards and practices, which continues today. Standards refer to explicit statements, guidelines, or codes published by organizations generally regarded to have influence or oversight on professional practices related to testing.

Perhaps the most widely recognized statement of professional standards is termed the *Standards for Educational and Psychological Testing*. These standards were originally produced by a joint committee representing AERA, APA, and the National Council on Measurement in Education (NCME) in 1966. Four subsequent versions were released since then, the most recent of these in 2014. It would be difficult to overstate the scope and reach of this document, which is commonly (and hereafter) referenced as simply: *the Standards*.

The Standards represent an important step forward in establishing guidelines for professional practice not solely because of the influence of the joint sponsors. Perhaps more importantly, contemporary editions of *the Standards* represented the first substantial initiative to go beyond calls for transparency in technical documentation and address the ethics of testing practices. As stated in the introduction of the 2014 edition, “the purpose of the standards is to provide criteria for the development and evaluation of tests and testing practices and to provide guidelines for assessing the validity of interpretations of test score for the intended test uses (American Educational Research Association et al., 2014, p. 1).

Given the influence of *the Standards* and recognizing that the sponsoring organizations are based in the United States, it is worth asking to what extent the standards have implications more globally. Zumbo (2014) explores this question and concludes that both the surface features and content position the document as useful across borders. He observes, “except for the translation into a language other than English, one would have to do very little to make the Standards international” (p. 32). Further, Zumbo notes that although the standards are not widely cited in academic literature overall, the frequency of citations in the US versus international journals is similar (p. 32). Additionally, the *Standards*, according to Zumbo, “play an important pedagogical role” in other countries because they cover foundational topics of common interest across borders (p. 32). Finally, their global spread may be indicative of the fact that the sponsoring organizations have many influential international members (Zumbo, 2014).

Notwithstanding the broad influence of *the Standards*, many other organizations have sponsored testing standards and guidelines. For example, the Association of Educational Assessment—Europe developed a set of standards for the European environment culminating in the publication of the *European Framework of Standards for Educational Assessment* (AEA, 2012). The framework is described as, “a practical instrument that test providers, users of assessment results and (educational) authorities can use to compare, contrast and evaluate practices in the development, administration, grading and reporting of a wide variety of assessments and assessment programs, and to review and present evidence that the methods used meet certain quality criteria” (2012, p. 11). The AEA framework emphasizes ethics, fairness, and rights of the individual and highlights the importance of validity, reliability, practicality, and impact on stakeholders (AEA, 2012).

Other initiatives fall into the category of providing more specific guidelines and recommendations for practice, often addressing a specific topic. For example, the International Test Commission (ITC) produces a number of professional guidelines addressing various testing practices such as: *The ITC Guidelines for Translating and Adapting Tests* (2017) or *The ITC Guidelines on Computer Based Testing* (2005). These and other documents produced by the ITC provide guidance and suggestions for practice, many of which build on and extend the work of *the Standards* among other sources.

In some cases industry standards and practices are more focused on implementation than development. For example, the Council of Chief State School Officers (CCSSO) and the Association of Test Publishers (ATP) collaborated in 2013 to produce the *Operational Best Practices for Large-Scale Assessment Programs*. As the name implies, these standards provide guidelines to “strengthen implementation” of assessment programs, in particular those developed to meet federal testing requirements in the United States (2013). Accordingly, the Operational Best Practices go into more detail than *the Standards* on issues such as test security, administration, scoring, reporting, and data management.

Testing organizations and sponsors

Another source for standards and guidelines related to educational measurement comes from organizations that develop or sponsor the tests. Some of these organizations are government agencies, others may be non-profit or commercial testing companies. Regardless, it is considered best practice for organizations to develop or adopt professional practices that are consistent with industry standards. Moreover, organizations should make technical information publicly available and work with experts to monitor, review and advise on technical and operational practices.

The monitoring and review functions are often fulfilled by expert technical advisors. In the best case these groups, which go by different naming conventions such as Technical Advisory Committees (TAC), comprise experts from various disciplines (e.g., psychometrics, accessibility, content development) who are external to and independent of the test developer or sponsor. Domaleski (2017) suggests TAC members should fulfill at least three roles: auditor, problem solver, and strategic partner. The auditor role

refers to the task of reviewing information or program activities, such as plans for a standard setting workshop or results from equating multiple forms, to ensure they are in keeping with established professional practices. The problem solver role refers to providing guidance with respect to a specific challenge, such as helping the client appropriately respond to the impact of a computer failure during testing. The strategic partner role places the TAC in a position to help identify new directions and innovations aligned to the organization's goals and priorities. For example, an organization may wish to transition a testing program that is based on fixed-forms to a computer adaptive format. The TAC may be asked to help develop a process including acceptance criteria to guide this initiative.

For example, the Organization for Economic Co-operation and Development (OECD), an inter-governmental organization comprising 38 member countries, sponsors the Program for International Student Assessment (PISA), a well-known international assessment of 15-year-old students in math, science and reading. OECD regularly and publicly disseminates technical reports and other documents to address standards, practices, and outcomes for the PISA program, such as the *Technical Standards and Guidelines* to, "contribute to creating an internal dataset of quality that allows for valid cross-national inferences to be made" (2018). Additionally, OECD convenes a Technical Advisory Group (TAG), "comprising independent, world-renowned experts in the field that underpin the PISA methodology, such as sampling, survey design, scaling, and analysis." The PISA TAG helps determine technical methods and procedures and provides guidance to ensure published results are useful for their intended purpose.

Similar examples could be presented to further illustrate how testing organizations or sponsors such as public agencies, companies, or collaboratives work to uphold standards through developing guidelines, disseminating public information, and enlisting the support of independent, expert advisors.

Government agencies

Although lines of distinction among groups such as professional associations, testing sponsors, and government can be unclear, government agencies are singled out in this section to describe some distinctive contributions to professional standards and guidelines, particularly related to regulation.

Heretofore, the sources and initiatives described are all voluntary and non-regulatory. There is not necessarily a formal consequence if a testing company decides to ignore widely-accepted professional standards, forgoes disseminating public information, or fails to seek counsel from independent advisors. Presumably, such behaviors would result in a loss of public confidence in the program and diminish support. However, there is no shortage of critiques about widely used assessments that raise questions about the scant evidence to support lofty claims, properties, purposes, or uses.

Enforcement, then, is largely the province of government agencies. In some cases, government agencies can fulfill that role by publishing their own laws, policies, guidelines, or requirements. For example, the United States Department of Education (ED) has produced a very influential document for state education agencies to meet the assessment requirements set forth in federal law—the Elementary and Secondary Education Act (ESEA). The document, informally referred to as simply, *Peer Review Guidance*, describes thirty elements for which states must assemble evidence to meet federal requirements (United States Department of Education, 2015). As the name implies, this evidence is evaluated by a panel of peer experts to judge whether it is sufficient. Failure to receive a favorable outcome could ultimately result in a loss of funding. While this outcome is rare, in practice, the *Peer Review Guidance* are the de facto principal set of guiding standards for American testing programs developed to meet federal law. Given the high stakes of failing to meet the standards, state agencies use this document to establish criteria for contractors that compete for lucrative testing contracts.

In other instances, government entities may be directly responsible for development and administration of assessments. Australia's National Assessment Program—Literacy and Numeracy (NAPLAN), which is overseen by the Australian Curriculum, Assessment and Reporting Authority (ACARA) provides an example of this practice. In this case, ACARA operates under a charter issued by the Australian Government's Education Council which outlines requirements for the development, implementation and monitoring of the NAPLAN. In turn, ACARA produces numerous reports to establish and communicate standards for development and implementation, such as the *Guidelines for the Development of Accessible NAPLAN Online Items* (2021). ACARA also produces annual technical reports and works with an independent advisory group, as addressed earlier in this article.

Another way that government agencies can both influence and enforce professional standards is through litigation. Accordingly, the corpus of case law from such litigation becomes yet another source of professional standards and practices. This is particularly germane when assessment is used for consequential or high-stakes purposes. O'Neill (2003) observes, "suits challenging high stakes testing programs have focused on a variety of factors, but the common denominator is fairness" (p. 634). For example, fairness may pertain to whether a test can be used as a diploma eligibility criterion or whether the outcomes are biased in favor of racial or ethnic groups. While a full review of legal precedent as pertains to testing is beyond the scope of this work, it is instructive to highlight the influence of some prominent cases.

While numerous cases in United States case law reveal that courts generally affirm the role of educational institutions to use assessments for consequential purposes, when property rights are at stake due process must be established (O'Neill, 2003). *Debra P. v. Turlington* (1981) is an oft cited case in which a Florida court determined that evidence of opportunity to learn and adequate notification must be established to warrant the use of a minimum test score as a diploma eligibility requirement. Another property right was adjudicated in *Bartlett v. New York State Board of Law Examiners* (2001); in this case the plaintiff sought extended time accommodations on a professional licensure test, the New York bar exam. The court ruled in favor of the plaintiff, which adds to the growing body of laws and public policy internationally that affirm the obligation to provide accommodations to examinees

with disabilities. For example, under the Equality Act of 2010 in the United Kingdom, education providers are required to make reasonable adjustments for students with disabilities, which includes educational assessment.

Principles

This section is intended to serve as a broad review of the core areas or principles that are often addressed from the body of contemporary professional standards and practices for testing. It is no small challenge to succinctly categorize or organize any description of the prominent areas addressed in professional standards, not least because most topics are cross-cutting. For example, an attempt to separate topics related to test validity from those related to test administration is confounded by the fact that administration is one factor that contributes to validity.

Ultimately, this section is organized using the same major sections in *the Standards*: foundations, operations, and applications. However imperfect, this may promote clarity and consistency with prevailing practice.

Foundations

Foundations refer to the canonical concepts of validity, reliability, and fairness. Validity is often regarded as the most important of the foundational concepts, in part because it is thought to subsume reliability and fairness (i.e., a test use that is not reliable or fair cannot be valid). However, as will be discussed in a later section of this article, the meaning and scope of validity continues to be a source of debate in the measurement field. In most cases, validity is typically described as the extent to which evidence supports the claim that a test measures what it is designed to measure and can be interpreted and used as intended (see e.g., McDonald, 1999; Kane, 2006). Professional standards that address validity typically emphasize the need for validity evidence to be (1) integrated across multiple areas (2) customized to the intended use(s) or inference(s) and (3) regarded as ongoing, insofar as validation is more of a process than an event. There are numerous frameworks for understanding and addressing validity that are beyond the scope of this article. However, most any credible attempt to address validity will draw on evidence connecting the stated purposes and claims of the test to evidence related to the development process, the content and structure of the test, the technical properties of the items and forms, the cognitive processes elicited, the relationship to external variables, and the manner in which results are communicated and used.

Reliability is often addressed in professional standards and generally refers to the extent to which results are stable or consistent for examinees across administrations under similar conditions. Reliability includes the concepts of precision or accuracy, often addressed by sources of evidence that may include: reliability or generalizability studies (e.g., internal consistency, test-retest, parallel forms, inter-rater consistency), reports of measurement error, and decision consistency studies. Standards typically call for these or similar sources of evidence to be produced for all relevant groups and conditions according to the intended nature and use of the test. For example, a test given on paper and computer must be equally reliable across both modes.

Like validity, the concept of fairness is both broad and often eludes a consensus definition with respect to its application to educational measurement. *The Standards* (2014) note of fairness, “fairness is a fundamental validity issue and requires attention throughout all stages of test development and use,” (p. 49). Commonly, professional standards related to fairness will address issues of inclusion, such as requirements to ensure that tests are developed, designed, administered, and scored in a manner to maximize accessibility. Moreover, the process should work to minimize barriers for all examinees such as by applying the principles of universal design in item and form development and ensuring appropriate accessibility features and accommodations are available (e.g., for students with disabilities or language learners). The concept of fairness also includes procedures to screen items and forms for differential performance by examinee group using both empirical and judgment-based procedures. Differential Item Functioning (DIF) studies are a common source of evidence to evaluate items for disparate impact among examinee groups and item bias and sensitivity reviews are typically employed to detect potential sources of bias.

More broadly, the issue of fairness also includes responsibilities of the test developer or sponsor to safeguard against uses that are inappropriate or potentially harmful. For example, test descriptions, documentation, and score reports should be accompanied by clear statements that indicate intended purposes, uses, and interpretations and, to the extent practicable, anticipate and caution against those that are not supported.

Operations

Operations refers generally to the wide-range of activities or steps involved in developing, administering, scoring, and reporting tests. A review of common sources for standards and practices consistently uncovers two dominant principles that emerge in this area. First, test developers have a responsibility to follow established, research-based practices. Second, developers have a responsibility to make supporting evidence available for review and scrutiny by experts and stakeholders.

The first principle speaks to the need to develop a clear rationale for the selected procedures and ensure that the methods in support of those procedures are grounded in a research-base such as from academic literature or established professional practices. For example, standards that pertain to scoring open response items address steps widely-supported in research and deployed in practice such as developing clear scoring rubrics and protocols and providing scorer training to include qualifying and ongoing monitoring. As another example, when judgment-based cut-scores are established for assessments, relevant standards address

the importance of selecting qualified participants, providing feedback throughout the process, and quantifying variation in judgments. Particularly when tests are used for high-stakes or consequential purposes, it is ill-advised to draw on new, unverified methods and procedures.

The second principle consistently found in a review of operational standards is the need for clear documentation and review throughout the cycle of test development and implementation. In fact, nearly every standard statement in *the Standards* is framed as a call to provide description, information, evidence, etc. in support of a particular decision, attribute, or claim. This includes nearly every operational task from developing the test blueprint to determining specifications for field testing to defending methods for score equating. In fact, numerous standards across multiple sources call for cross-validation, review, and transparency. As noted previously, strong practices for test developers or sponsors call for not only widely disseminating information publicly, but also engaging independent experts to advise on program decisions and conduct ongoing monitoring.

Applications

Heretofore, most of the standards and practices discussed have centered responsibly on test developers or sponsors. However, it is also important to recognize the ethical principles and practices primarily, but not exclusively, under the purview of test users. In education, test users may refer to such personnel as district or school administrators, counselors, or classroom teachers. The principles related to applications cut across many areas previously described focusing on responsibilities related to being appropriately credentialed and trained to fulfill expectations, complying with relevant standards and policies (e.g., related to security and confidentiality), and interpreting and using results in a responsible manner consistent with the intended purpose of the test. For example, responsible test use requires being informed about the error associated with test scores and factoring this information into decisions, such as by corroborating scores with other sources to inform consequential decisions.

Issues and future directions

There is no shortage of opinions about the current state of professional standards for educational measurement. This section acknowledges some of the prominent critiques, related to both content and process, and identifies some emerging focus areas in the short and longer term.

Starting with the content, one criticism of the standards is that the manner in which construct representation is addressed impedes progress toward more culturally sustaining assessment practices. Jennifer Randall argues for redefining construct definition and representation from an antiracist perspective contending that current methods, “provide the illusion of fairness, but in reality, these practices serve only to support the current white supremacist hegemony” (2021, p. 4). Randall urges the field to rethink so-called “color-neutral” approaches that are reified in the standards.

This critique relates to broader and growing area of concern about the extent which prevailing standards do, or should, address the wider range of ethical or social consequences associated with test use. Newton and Shaw (2015) describe this tension as it manifests in widely different perspectives in the field about the meaning of validity. The authors contrast more conservative positions that are primarily focused on validity from a narrower technical perspective to more liberal views that may address “overall defensibility, or acceptability, of the policy which sanctions the use of test scores for a particular purpose” (2015, p. 4). The latter view has given rise to the term “consequential validity,” the meaning of which is widely debated, but it is often used to describe the necessity of evaluating the extent to which any benefits of testing outweigh the negative consequences.

This lack of clarity, illustrated by the competing views about validity, is not simply academic. It gives rise to very real and practical questions about the scope of professional standards and ethics. As society increasingly grapples with the role of tests in educational policy and practice, questions about how professional standards can or should address these uses and who bears responsibility require an answer. For example, results from achievement tests are increasingly used as prominent components of high-stakes school accountability systems. Should professional standards address these uses in part or whole? If such a use falls outside that which is supported by the test developer, the assumption is that the responsibility falls to the organization that adopts or implements the policy. Importantly, *the Standards* caution, “If a test score is interpreted for a given use in a way that has not been validated, it is incumbent on the user to justify the new interpretation for that use, providing rationale and collecting new evidence, if necessary” (p. 24). Additionally, NCME released a position statement in 2020 calling for program sponsors, designers, or users to take responsibility for developing theories of actions for consequential test uses designed to effect change. Such theories of action should “document and disseminate arguments and evidence in support of the expected (causal) relationships among the program’s constituent parts, the implementation actions, and the intended outcomes, and also plan for ongoing evaluation” (2020, p. 1).

However, it is reasonable to ask if professional associations or others should do more to support such endeavors. As Sinharay et al. (2014) observe about *the Standards*, “In our opinion, the Standards are useful to a certain extent in guiding researchers in our field with respect to general principles, but lack the type of specific guidance that practitioners often need. The Standards are thus more academic than pragmatic” (p. 36). This critique suggests that priorities for future contributions to professional standards should provide more specific guidance about how to assemble a coherent and convincing collection of evidence to support prominent uses.

Consider, too, that contemporary professional standards rely almost exclusively on professional judgment to judge the adequacy of evidence. Questions such as what constitutes adequate alignment or what level of rater agreement is acceptable are largely left to

the province of either convention or judgment. While it is unreasonable to expect sufficient clarity from professional standards and guidelines to direct all decisions related to development, implementation, and use, the field will likely benefit from ongoing efforts to create and disseminate more guidance about both cautions and promising practices. This is likely to be especially beneficial when directed to both test developers and a range of users, such as educators, leaders and policy makers.

Introduction

Reliability is a key concept in the measurement of psychological attributes, such as the central intelligence ability of analytical reasoning and the personality trait of neuroticism, educational attributes, such as arithmetic ability and knowledge of American history, and health attributes, such as quality of life and pain experience. Reliability refers to the degree to which measurement values obtained from repetitions of the measurement procedure using the same test or questionnaire in the same population are equal. Different approaches to reliability exist that depart from slightly different definitions and develop different formal estimation procedures. Classical test theory (CTT) provided the traditional approach that focuses on single tests administered once in one population. Generalizability theory (GT) is a broader approach that identifies variance sources other than the attribute of interest that affect the relative or absolute measurement of persons and enables adapting the test procedure to reduce these sources while increasing reliability. Factor analysis (FA) takes a factor model as a point of departure, often a common-factor model, and defines reliability based on person variance with respect to the common or other factors. Item response theory (IRT) has also proposed reliability approaches, but in IRT the focus is on the information function conditional on the scale of measurement.

Our examples discussed next refer to the repeatability of an individual diagnosis and an individual test score, mainly because this optimally allows explaining the idea behind reliability. However, when referring to an individual result, the correct terminology is measurement precision, whereas reliability refers to a group characteristic (Mellenbergh, 1996). Measurement precision expresses the statistical precision of estimating an individual's measurement value and varies across the scale of measurement. Using a particular arithmetic test, John's test score may be estimated with less precision than Mary's. The reason for this apparent discrepancy is that the mean arithmetic level the test represents aligns better with Mary's level than with John's. For example, if the test is difficult

and Mary has a high arithmetic ability, the estimation of ability is relatively precise, whereas the estimation of John's ability, which is well below the test's level is less precise than Mary's. Reliability is a group characteristic summarizing individuals' differences in measurement precision at a higher aggregation level. In each approach, reliability expresses the ratio of the variance in a group relevant to person measurement and this variance plus sources considered irrelevant for person measurement. For example, in the FA approach, reliability can be the proportion of variance the common factor explains in the variance the total factor model explains. Because reliability is an aggregated quantity, a reliable test or questionnaire can still measure some individuals' performance with little precision and an unreliable instrument can be precise for some other individuals.

In this entry, for the CTT, GT, FA and IRT approaches to reliability, we discuss the test design, the model for reliability, methods for estimating reliability, and measurement precision aimed at the measurement of individuals. We point out the approaches' similarities and differences. We end with a typology of the four approaches emphasizing their differences but note that each has its specific merits and applications.

Classical test theory

Test design

Reliability defined by CTT expresses the degree to which a measurement value is repeatable under the same measurement conditions in a population of people. Classical reliability aligns very well with the classical question in statistics: What would happen when I do it over again? While in statistics the question refers to drawing a new random sample and assessing the degree to which statistical results are different from initial results, it is also well applicable in daily life (e.g., Lord and Novick, 1968, pp. 29–30). For example, consulting your family doctor about a resistant cough, you expect her to come up with the same diagnosis irrespective of the occasion of your visit. If she would diagnose your cough as a mild cold on Tuesday and a serious bronchitis on Wednesday, simply having forgotten that she saw you a day earlier—admittedly, not a likely assumption but needed to mimic statistical independence—you would probably feel uneasy about her trustworthiness or reliability. Similarly, an intelligence test that would diagnose you one day a mediocre person and the next day as highly intelligent would raise some eyebrows. In both cases, reliability of measurement seems to be low. Statistically, in these cases, the predictability of the measurement upon repetition is poor, a result one wishes to avoid.

The measurement value can be anything, ranging from the score on individual items to total scores on subsets of items assessing different subattributes and on the whole item set, but also response times and assessments raters provide of educational tasks. Repeatability under the same conditions refers to controlling the administration circumstances for the test or the questionnaire, such that only random events influence performance on the test or the questionnaire. Controlling the administration circumstances is known as standardization and is key to reliable measurement. Reliability is defined on a well-defined population of people and expresses the degree of measurement repeatability in this population. Reliability of measurement for a particular test or questionnaire varies across different populations and across subgroups from one population. It is important to note that a test or questionnaire does not have one reliability but as many reliabilities as there are populations in which the test is used. A test or questionnaire that is reliable in the group of all high school grades may be unreliable in one high-school grade. A test or questionnaire administered may have a different reliability under different administration procedures. For example, it may make a difference whether the test was administered in high-stakes or low-stakes conditions. In both situations, motivation may be different, affecting test performance.

Model

Let X_j be the score on item j , and let the test or questionnaire consist of J items, so that items are indexed $j = 1, \dots, J$. Let the total score on the J items be

$$X = \sum_{j=1}^J X_j.$$

CTT splits the test score into the true score, denoted T , and a random measurement error, E , so that

$$X = T + E.$$

Assume that it is possible to administer the test repeatedly to the same group of people under precisely the same circumstances assuming that everybody's attribute level stays fixed between administrations. Then, between administrations, test scores vary only due to random measurement error. For individual i , in administration r , the model would be

$$X_{ir} = T_i + E_{ir},$$

where her true score is defined as the expected value across test scores obtained in different test administrations,

$$T_i = \mathcal{E}_r(X_{ir}).$$

In a population of people, the reliability of test score X is defined as the proportion of test-score variance, denoted σ_X^2 , that is true-score variance, denoted σ_T^2 . Reliability is denoted $\rho_{XX'}$, so that

$$\rho_{XX'} = \frac{\sigma_T^2}{\sigma_X^2}.$$

Given that reliability is a ratio of two positive numbers, it cannot have negative values. If $\sigma_T^2 = 0$, that is, if all persons have the same true score, reliability equals zero; that is, $\rho_{XX'} = 0$. If all test-score variance equals true-score variance, $\sigma_X^2 = \sigma_T^2$, then reliability equals 1; that is, $\rho_{XX'} = 1$. Because CTT assumes random measurement error covaries zero with all other variables including true scores, that is, $\sigma_{ET} = 0$, one can derive that

$$\sigma_X^2 = \sigma_T^2 + \sigma_E^2,$$

and reliability can also be written as

$$\rho_{XX'} = 1 - \frac{\sigma_E^2}{\sigma_X^2}.$$

From this equation one can derive that $\rho_{XX'} = 1$ also if measurement-error variance equals zero; that is, $\sigma_E^2 = 0$. Because from the definition of the true score, we can also derive that for individual i ,

$$\mathcal{E}_r(E_{ir}) = \mathcal{E}_r(X_{ir} - T_i) = 0,$$

across individuals we find that the mean measurement error equals

$$\mathcal{E}_i(E_i) = 0.$$

Thus, variance $\sigma_E^2 = 0$ and expectation $\mathcal{E}_i(E_i) = 0$ together imply that all measurement errors equal zero, and $X_i = T_i$, for all individuals. Therefore, reliability equal to 1 implies that the test scores are without random measurement error.

To summarize, we have that

$$0 \leq \rho_{XX'} \leq 1.$$

The definition of reliability is an equation with two unknowns. On the right-hand side, either σ_T^2 or σ_E^2 are unknown, so that we cannot compute the left-hand side, $\rho_{XX'}$. Many methods have been proposed to estimate reliability by approximating σ_T^2 or σ_E^2 using only parameters that can be estimated directly from the data. Using these methods, for real tests and questionnaires, it is common to find values of at least 0.7, but for well-constructed tests and questionnaires values greater than 0.8 or 0.9 are attainable. Reliability almost equal to 1 is possible in principle when one lets the number of items grow without limit, clearly unattainable in practical applications due to person fatigue, time constraints, and item shortage.

A result we will encounter later in this entry discussing IRT reliability, is the equation

$$\rho_{XX'} = \rho_{TX}^2,$$

where the right-hand-side is the squared correlation between test score and true score. Correlation $\rho_{TX} = \sqrt{\rho_{XX'}}$ is known as the reliability index. It provides an upper bound to the correlation test score X can have with any other variable $Y \neq T$. It also plays a theoretically important role in regression approaches to CTT.

Methods

The best-known method for estimating reliability based on only observable variables, is coefficient α (Cronbach, 1951; first proposal by Kuder and Richardson, 1937). We focus on the test score based on the individual items in the test or questionnaire. Let the covariance between the item scores X_j and X_k be denoted σ_{jk} . Based only on assumptions of CTT applied to individual item scores, it can be proven that the next inequality holds (Novick and Lewis, 1967; Ten Berge and Sočan, 2004),

$$\alpha = \frac{J}{J-1} \frac{\sum_{j \neq k} \sigma_{jk}}{\sigma_X^2} \leq \frac{\sigma_T^2}{\sigma_X^2} = \rho_{XX'}.$$

The left-hand side of the inequality is coefficient α . The inequality shows that theoretically coefficient α is always smaller than or equal to reliability $\rho_{XX'}$. Unlike the right-hand side, which contains unobservable true-score variance σ_T^2 , coefficient α depends on the inter-item covariances σ_{jk} and test-score variances σ_X^2 , parameters that can be estimated from the data.

Equality $\alpha = \rho_{XX'}$ is obtained when the items are highly similar, which is mathematically defined as essential τ -equivalence (Lord and Novick, 1968) and too strict for items in practical applications. Hence, for real tests and questionnaires, at the population level, coefficient α is a lower bound to the reliability, $\alpha < \rho_{XX'}$. For item sets that are approximately unidimensional sharing a common factor, coefficient α is nearly equal to the reliability, $\rho_{XX'}$. Estimates of coefficient α are nearly equal to the true reliability. For clearly multidimensional data, coefficient α seriously underestimates reliability. The test constructor may consider whether having a test

score that expresses several attributes simultaneously is desirable. Estimates of α based on unidimensional item subsets would be close to reliability.

Many lower bounds for reliability exist that depend only on observable statistics (Guttman, 1945; Ten Berge and Zegers, 1978). For example, coefficient λ_2 is marginally higher than coefficient α and may be used alternatively. Other coefficients are greater lower bounds than coefficients α and λ_2 , but are based on optimization of sample characteristics including sampling error, known as chance capitalization, and as a result tend to overestimate true reliability seriously. One of these lower bounds readily producing overestimates is method λ_4 (e.g., Guttman, 1945; Jackson and Agunwamba, 1977), which is based on the historically well-known split-half method, and Hunt and Bentler (2015) demonstrate how to adapt the estimation procedure such that estimates are nearly equal to the reliability. The greatest lower bound (GLB; Bentler and Woodward, 1980; Woodward and Bentler, 1978) is theoretically the lower bound closest to the true reliability, but like method λ_4 , the GLB is known to overestimate reliability especially when sample sizes are smaller than 1000 and numbers of items are at least 10. Oosterwijk et al. (2017) provide more information about lower bound methods overestimating reliability in real data.

Other methods for estimating reliability having a longer tradition in test construction tend to be less efficient than the lower-bound methods but are still in use. They all mimic the idea that reliability should inform about the degree to which the test score is repeatable in a group when administered more often to the same group under the same administration procedure. We discuss the best-known methods next.

The retest method is based on two test administrations with a time interval in between that suits the researcher's purposes. The interest is with the correlation between the two sets of test scores collected, expressing the degree to which the test performance is repeatable or stable across the chosen time interval. Obviously, in this setup, all changes that take place in the individuals between the two administrations relevant to the measured attribute exert their influence on the correlation. Examples are developmental effects, learning effects, but also memory of the items answered at the first administration when presented at the second administration. Moreover, it has been suggested that across time attributes may become factorially more complex (Embretson, 1991), thus changing the meaning of measurement. At least, the retest method provides an impression of the measurement's stability across a given time interval. The retest method is expected to produce values smaller than the reliability, $\rho_{XX'}$.

The parallel-test method circumvents many of the problems discussed with the retest method by administering in the same session two different tests for the same attribute that are interchangeable with respect to content, such that they are also interchangeable with respect to their psychometric properties. We refrain from defining this mathematical convertibility known as parallelism but note that the theoretical correlation between the two sets of test scores obtained from two parallel tests, denoted X and X' , is precisely equal to the reliability of either test version. This correlation is denoted $\rho_{XX'}$, which explains the notation we introduced previously without further ado. Because two parallel tests can be shown to have the same reliabilities, we write

$$\rho_{XX'} = \frac{\sigma_T^2}{\sigma_X^2} = \frac{\sigma_{T'}^2}{\sigma_{X'}^2}.$$

The practical problem with the method is the construction of two test versions that are parallel without the items looking like copies of one another. One of the complexities of the measurement of human attributes are the badly understood intricacies of cognitive and affective systems reacting to complex stimuli like the items from a test or questionnaire. Correlations between test scores obtained from tests intended to be parallel are expected to be smaller than reliability, $\rho_{XX'}$.

The split-half method is an efficient version of the parallel-test method, where the test constructor divides the set of items into two halves that she assumes function as parallel half-tests. The correlation between the total scores on the two halves is an estimate of the reliability of a test half the length of the intended test. The Spearman-Brown prophecy formula, assuming that the halves are parallel, can then be used to estimate the reliability of a test twice the length of half a test; that is, a test as intended having length J . Although more efficient than the parallel-test method because it uses only half the number of items, the split-half method suffers from the same problems. Most important, test halves are not precisely parallel. In addition, there are many ways to construct test halves or near test-halves, each producing different correlations. Guttman's coefficient λ_4 provides a way out of these problems and Hunt and Bentler (2015) propose an estimation procedure taking it close to the true reliability.

Revelle and Condon (2019) and Sijtsma and Van der Ark (2021, Chap. 2) provide up-to-date overviews of CTT reliability estimation methods.

Real-data example

We used the correct/incorrect (1/0) data from 24 four-choice items comprising an educational test in psychological test theory. The test was administered to 247 second-year undergraduate students in psychology at Tilburg University in 2013. The data were used previously by Van der Palm et al. (2014). We deleted one invalid case that was accidentally included in the original file ($N = 248$) and one item that was answered correctly by all students, so that $J = 23$. For 247 students answering 23 items, we found $\hat{\alpha} = 0.546$ and $\hat{\lambda}_2 = 0.568$, the latter result marginally greater, consistent with expectation. In addition, $\hat{\lambda}_4 = 0.731$, and following Hunt and Bentler (2015), the λ_4 estimates based on the 5th, the 50th, and the 95th percentile of the estimated sampling distribution equaled 0.624, 0.669, and 0.707. Hunt and Bentler (2015) suggested using the 5th percentile estimate, which they claim protects best against overestimation while being close to the true reliability. The GLB estimate was 0.747.

Coefficients α and λ_2 provide almost unbiased estimates of reliability $\rho_{XX'}$ when the item set has a one-factor structure, but the λ_4 variations and the GLB capitalize on chance and tend to overestimate the reliability. Educational tests administered at universities are constructed to cover highly heterogeneous knowledge domains rendering a multi-factor structure likely. An exploratory minimum-residuals two-factor analysis produced five items loading higher than 0.3 on the first Varimax rotated factor and six items loading at least 0.3 on the second factor, with a maximum loading of 0.49. For a three-factor solution the numbers of items were four, four, and two, with a maximum loading of 0.62. For multi-factor structures, coefficients α and λ_2 provide reliability underestimates, but the coefficient λ_4 variations and the GLB tend to overestimate reliability seriously. Given the messy factor structures, we did not attempt to estimate reliability for item subsets or based on methods taking multiple factors into account.

Measurement precision

A reliability equal to, say, 0.85, may seem quite satisfactory but represents a group characteristic, leaving the issue open whether the test or questionnaire measures individuals with enough precision. A simple but crude approach is using the standard error of measurement (SEM),

$$\sigma_E = \sigma_X \sqrt{(1 - \rho_{XX'})},$$

derived directly from the definition of reliability. Inserting sample standard deviation S_X and an estimate for $\rho_{XX'}$ provides an estimate of the SEM, denoted S_E . The equation of the SEM contains only group characteristics. Hence, similar to reliability, the SEM is a group characteristic providing the same measure of imprecision for each tested individual. In the simplest case, assume that we take the test score as an estimate of the true score, and we assume that across independent repetitions the distribution of person i 's test scores is normal and except for mean T_i varies across individuals with the same standard deviation, estimated by means of S_E . A 95% confidence interval equals

$$[\hat{T}_i - z_{(\alpha/2)} S_E; \hat{T}_i + z_{(\alpha/2)} S_E],$$

where α is the 5% significance level used to test the null hypothesis that $T_i = X_i$. Another approach known as Kelley's formula uses a regression model for estimating the true score. The model uses group characteristics to transform the test score to a true score estimate and like the SEM, the regression approach provides a residual standard error that is the same for everyone.

The weakness of the SEM approach to measurement precision is that it assigns the same measure of imprecision, σ_E (and the regression residual standard error), to everyone irrespective of whether the test or questionnaire matches the individual's attribute level. For example, an easy arithmetic test is more informative of a student having low arithmetic ability than a student with a higher level. Because the latter student gives a positive response to most items, we only know that her level is higher than the items' levels, but we need more difficult (ability) or less popular (trait, attitude) items to pinpoint the individual's scale position. [Sijtsma and Van der Ark \(2021, pp. 80–82\)](#) discussed methods for estimating scale-dependent SEMs; also see [Feldt et al. \(1985\)](#). [Lek and Van de Schoot \(2018\)](#) studied SEMs for subgroups and individuals and recommended the following. An individual-dependent SEM presumes many items enabling several "parallel" subtests with approximate continuous subtest scores, conditions rarely realistic. In other cases, a SEM conditional on subgroups may be appropriate when a relationship exists between the true score and the conditional error variance. Otherwise, the overall SEM is in order.

Comments

A CTT feature often overlooked is that CTT is an error theory but not a latent variable model that seeks to explain the relationships among a set of items. At the level of items, for items j and k , CTT equals

$$X_j = T_j + E_j \text{ and } X_k = T_k + E_k.$$

For individuals, the item true-scores are expectations across independent repetitions of the same items, but there are no model features such as latent variables that dictate the items must have something in common. To modern-day test constructors and researchers using tests and questionnaires this may seem odd, but they should realize that they are the actors who select a set of items that purport to measure the same attribute, collect data, and then use principal component analysis or factor analysis to assess whether the items measure enough in common to constitute one scale. Principally, it is only then that CTT is brought in to estimate the reliability of the test score. Of course, CTT has produced many methods to help construct a useful test or questionnaire, but as an error theory, it basically is concerned with reliability but not with what items or other test parts measure in common. FA and IRT do assume items or test parts to have one or more latent variables in common, and in this respect are different from CTT. Still, the fact that a set of items have a latent variable in common does not logically imply they measure the attribute of interest. As with CTT, it is up to the researcher to establish this as part of validity research.

The fact that modern-day psychometrics has embraced latent variables as explanatory tools underlying sets of observable variables has convinced several psychometricians they should view CTT and reliability from the perspective of latent-variable models, especially FA. Hence, the true score is considered a latent variable that the items have in common. The condition of essentially τ -equivalent items is interpreted as a 1-factor model, and because the 1-factor model is too restrictive to fit a data set, coefficient

α is criticized for not equaling true reliability. This result is the main reason why adherents of other approaches reject coefficient α and other CTT-based reliability methods in favor of other approaches mainly based on FA. We have argued that coefficient α simply does what it is supposed to do, but that it tends to underestimate reliability when data are multidimensional, a situation confounding different attributes test constructors often wish to avoid. One may consult recent discussions on reliability; see [Sijtsma \(2009\)](#), [Cho and Kim \(2015\)](#), [McNeish \(2018\)](#), [Raykov and Marcoulides \(2019\)](#), [Revelle and Condon \(2019\)](#), and [Sijtsma and Pfadt \(2021\)](#). [Mellenbergh \(1998\)](#) developed the idea of one latent variable in the context of CTT and studied test-score reliability for the estimated latent variable.

Generalizability theory

Test design

Chronologically, GT was the next approach to reliability, dating back to the 1950s. Its first full account was given by [Cronbach et al. \(1972\)](#). CTT defines and estimates reliability of test scores based on one test administered on one occasion and scored by one rater in case of constructed-response items. One may think of a set of items assessing reading ability at the beginning of the school year that is the same for each student tested, and one rater who scores the responses the students provide. One could argue that the test score is only interesting to the degree it generalizes across item sets, raters, and occasions, but other facets—sources of test-score variation—may be of interest depending on the purpose of testing. When different item sets, raters, and occasions, and possibly combinations of these facets produce different test scores, the exact conditions under which a test is administered are important for the result, but one may wish the assessment of test performance were independent of these rather arbitrary conditions and adapt the test to minimize their influences.

GT defines the sources that influence test performance in addition to people's attribute as error sources. The test constructor wishes to minimize the influence of these error sources on the test's reliability. Based on a design including the facets and the facet conditions of interest for collecting data, the generalizability (G) study estimates the variance components each of the error sources contribute to the total-score variance, and for large variance components the decision (D) study assesses how the test should be adapted to optimize reliability. Not the single test score that is of interest to CTT is of interest to the purpose of testing as adopted by GT, but the mean score taken across the levels or conditions of the different facets. This mean score is known as the universe score, which parallels CTT's true score. The question addressed in GT is how to assemble the test and the conditions for its administration so that an estimate of people's universe scores is obtained.

In the G study, GT identifies different sources of variance, in the example attributable to item sets, raters, and occasions, their two-way and three-way interactions, and a combined variance component for four-way interactions, unexplained sources of test-score variance and random measurement error. The latter component reflects the confounded influence of various sources on test performance that the designs do not allow to be disentangled. The variance components are used to estimate two kinds of reliability, one assessing the relative interpretation of test performance, by which GT means the ordering of persons relative to one another, and the other assessing the absolute interpretation of individuals' test performance independent of other people's test performance. CTT only considers random measurement error as an error source and all other variance as true-score variance and defines and estimates reliability for relative measurement. Depending on the relative or absolute interpretation of test performance, GT reliability is based on a variance decomposition different from that of CTT.

GT's contribution is to identify the various variance components based on a factorial design for collecting data and estimate a coefficient that corrects for these components depending on the kind of person assessment. The smaller the error variances, the higher the reliability and the more generalizable the test performance across the identified facets to universe scores.

Model

We limit attention to two facets considered relevant, which are item sets and raters. By relevant we mean that we suspect one fixed item set and one arbitrarily chosen rater to be insufficient for reliable measurement. Therefore, we prefer to study the degree to which different item sets and raters affect reliability and based on this information how to improve the test, for example, by using more items and raters. We discuss the GT model for two random facets, item sets and raters, in a crossed design. Let X_{ijr} be the score of person i on item j ($j = 1, \dots, J$) scored by rater r ($r = 1, \dots, R$). Persons are the objects of measurement and item sets and raters constitute potential sources of error we wish to estimate and use for improving the test.

Score X_{ijr} is decomposed into effects of facets represented in the design according to analysis-of-variance logic. This yields a person effect, an item effect, a rater effect, three two-way interaction effects, and a residual effect. The residual represents both the three-way interaction and all the effects not represented thus far; that is, effects stemming from facets relevant to the generalization not included in the design and all other systematic and random influences. Let μ be the grand population mean, defined as $\mu = \mathcal{E}_i \mathcal{E}_j \mathcal{E}_r (X_{ijr})$, let $\mu_i = \mathcal{E}_j \mathcal{E}_r (X_{ijr})$ be the mean for person i or her universe score, and so on; then

$$\text{Main effects: } X_{ijr} = \mu + (\mu_i - \mu) + (\mu_j - \mu) + (\mu_r - \mu) +$$

$$\text{Two-way interactions: } + (\mu_{ij} - \mu_i - \mu_j + \mu) + (\mu_{ir} - \mu_i - \mu_r + \mu) + (\mu_{jr} - \mu_j - \mu_r + \mu) +$$

$$\text{Residual effect : } + (X_{ijr} - \mu_{ij} - \mu_{ir} - \mu_{jr} + \mu_i + \mu_j + \mu_r - \mu).$$

We assume that each effect has a distribution. For example, the universe scores μ_i have mean equal to 0 and positive variance, reflecting person variance with respect to, for example, reading ability. The total variance of all X_{ijr} scores in the design can be decomposed in

$$\sigma_{X_{ijr}}^2 = \sigma_i^2 + \sigma_j^2 + \sigma_r^2 + \sigma_{ij}^2 + \sigma_{ir}^2 + \sigma_{jr}^2 + \sigma_{ijr,e}^2.$$

The residual variance, $\sigma_{ijr,e}^2$, represents all variation due to the three-way interaction and all unaccounted influences, systematic and random, impossible to disentangle because design cell (i, j, r) contains just one observation X_{ijr} . Variance σ_i^2 is the variance of the universe scores and shows the degree to which persons vary with respect to reading ability. Variance σ_{ij}^2 for person-by-item interaction represents the extent to which different item sets order persons differently, and so on. These variance components are the basis for estimating reliability based on a relative or an absolute interpretation of test performance. How this is done precisely depends on the design, which may be fully crossed (or incomplete), nested, (un)balanced, random/fixed or based on any combination of these possibilities, comparable to the large variety of experimental designs known from analysis-of-variance methods (e.g., [Winer, 1962](#)). Given the space admitted in an encyclopedia, we limit ourselves to the completely-crossed random two-facet design we discussed thus far.

Methods

Variance components are estimated using methods well known from analysis of variance. See [Shavelson and Webb \(1991\)](#) for a primer, and [Brennan \(2001\)](#) for an advanced treatment of GT using analysis-of-variance methods. The computations are beyond the scope of this entry, so we confine the discussion to noticing that one starts the computations with the sums-of-squares, then divide by the appropriate number of degrees of freedom to obtain the mean squares, and then derive the expected mean squares, which are functions of the unknown variance components desired. The result is a set of K equations from which K variance components can be solved. These variance estimates are the input for reliability estimation. In what follows, we assume we have the variance components available and focus on reliability. Two possibilities exist, one for relative person measurement and one for absolute person measurement, the first producing a *generalizability coefficient* and the second an *index of dependability*. We focus on the general idea and refer the interested reader to the literature. The difference between the two coefficients resides in identifying variance sources that confound the relative measurement of the ordering of persons, the absolute measurement of persons, or both.

For relative measurement, obviously σ_i^2 is relevant, but the interaction sources including persons are not and, in this context, qualify as error. That is, a positive interaction variance between persons and item sets means that different item sets order persons differently, and a positive interaction variance between persons and raters means that different raters order persons differently. A positive three-way interaction variance, included in the residual variance, $\sigma_{ijr,e}^2$, means that different combinations of item set and rater order persons differently. However, a positive interaction variance between item set and rater means that different raters order item sets differently by mean item scores, but does not necessarily influence person ordering, hence does qualify as an error source relative to person ordering. The same conclusion holds for positive item set variance and positive rater variance; these variances show only that mean item scores computed across persons and raters vary ($\sigma_j^2 > 0$) and that mean rater scores computed across persons and items vary ($\sigma_r^2 > 0$). For other designs, different variance sources constitute error and lead to different generalizability coefficients and dependability indices.

For our completely-crossed random two-facet design example, the error variance, denoted as σ_{Rel}^2 (Rel for relative), equals

$$\sigma_{\text{Rel}}^2 = \frac{\sigma_{ij}^2}{J} + \frac{\sigma_{ir}^2}{R} + \frac{\sigma_{jr}^2}{JR}.$$

The denominators reflect that larger numbers of item sets and raters reduce error sources. This knowledge may be used in the D study to make optimal decisions about the design maximizing reliability. The other ingredient for determining generalizability is person variance, σ_i^2 . Following notational conventions in GT (e.g., [Brennan, 2001](#), p. 13), generalizability for relative measurement is defined as

$$\mathcal{E}(\rho^2) = \frac{\sigma_i^2}{\sigma_i^2 + \sigma_{\text{Rel}}^2} = \frac{\sigma_i^2}{\sigma_i^2 + \frac{\sigma_{ij}^2}{J} + \frac{\sigma_{ir}^2}{R} + \frac{\sigma_{jr}^2}{JR}}.$$

It is interesting to notice that the denominator is different from $\sigma_{X_{ijr}}^2$, the variance of all observed mean item scores collected in the design. [Shavelson and Webb \(1991\)](#) noticed that the denominator equals $\mathcal{E}_{ijm}(\sigma_{X_{ijm}}^2)$.

For absolute measurement, the error variance σ_{Abs}^2 (Abs for absolute) equals

$$\sigma_{\text{Abs}}^2 = \frac{\sigma_j^2}{J} + \frac{\sigma_r^2}{R} + \frac{\sigma_{ij}^2}{J} + \frac{\sigma_{ir}^2}{R} + \frac{\sigma_{jr}^2}{JR} + \frac{\sigma_{ijr,e}^2}{JR}.$$

Reliability for absolute measurement is now defined using the index of dependability and equals

$$\Phi = \frac{\sigma_i^2}{\sigma_i^2 + \sigma_{\text{Abs}}^2} = \frac{\sigma_i^2}{\sigma_i^2 + \frac{\sigma_j^2}{J} + \frac{\sigma_r^2}{R} + \frac{\sigma_{ij}^2}{J} + \frac{\sigma_{ir}^2}{R} + \frac{\sigma_{jr}^2}{JR} + \frac{\sigma_{jre}^2}{JR}}.$$

Given that the error term in the index of dependability Φ contains more variance components than in the generalizability coefficient $\mathcal{E}\rho^2$, one will often find smaller values for Φ .

Real-data example

We did not provide GT reliability estimates for real data because we would need data collected based on a factorial design, different from the data used in the CTT section. We do not have such more complex data available, but for easily accessible data examples refer the reader to [Shavelson and Webb \(1991\)](#).

Measurement precision

[Brennan \(2001\)](#) discussed standard errors of measurement for relative and absolute measurement in several designs. He also discussed GT approaches to conditional measurement precision. These discussions are important but beyond the scope of this entry.

Comments

Conceptually, GT is more complex than CTT. Whereas CTT focuses on one measurement instrument that is administered to a particular population under well-defined conditions, GT asks what happens to measurement when each of these characteristics and others deemed relevant are varied. Thus, GT assesses reliability—generalizability and dependability in GT parlance—of estimates of universe scores obtained across the various conditions, which replace true scores. Variation in measurement caused by variation in facet conditions is considered error that confounds measurement in the sense that it reduces reliability. A G study is used to estimate the variance components in the total-score variance due to the choice of items and the choice of raters. Depending on the application of the planned measurement instrument and based on the results, new estimates are made of the variance components when the numbers of items and raters are increased. Next, a D study is used to estimate reliability for relative and absolute measurement. The outcomes determine test length and deployment of raters. Thus, the D study determines the final measurement instrument.

Facets discussed in treatments of GT are usually quantitative, such as numbers of item sets and raters, but an interesting question is how GT handles qualitative facets, such as different presentation modes for the items. Suppose a test constructor wonders whether the measurement of reading ability depends to some degree on item presentation in multiple-choice mode or constructed-response mode. When there are only two conditions for the facet of presentation mode, if it is included in the design, it is a fixed facet, which by itself does not pose a problem to analysis of variance. The problem here is that conceptually it is difficult to imagine how the test procedure should be adapted if the variance component for presentation mode is large; surely not by increasing the number of different presentation modes. [Shavelson et al. \(1989\)](#) and [Briesch et al. \(2014\)](#) suggest approaches that do justice to qualitatively different item-presentation modes in the context of GT.

Factor analysis

Test design

One administers a test or questionnaire once to a group of persons, comparable to the test design discussed for CTT. The resulting data are the input for a reliability estimation using FA methods.

Model

Unlike CTT, FA models the relationship between pairs of items j and k in a test or a questionnaire by means of one or more latent variables, in the context of FA called factors, as ([Bollen, 1989](#))

$$X_j = b_j + \sum_{m=1}^M a_{jm}\xi_m + \delta_j \text{ and } X_k = b_k + \sum_{m=1}^M a_{km}\xi_m + \delta_k.$$

The latent variables are denoted by ξ_m , with $m = 1, \dots, M$. Each item has a loading on each latent variable, denoted a_{jm} , indicating the strength of the relationship between the item and the latent variable, and an intercept b_j that represents the item's difficulty or (lack of) popularity. Residual δ_j represent unexplained systematic score components and random measurement error. In a multidimensional model, some latent variables may be unimportant for some items, in which case loading $a_{jm} \approx 0$. For example, for some arithmetic items, language skills may play a role while for other items language is immaterial for solving the problem. In a unidimensional model, only one common latent variable is of interest and $M = 1$.

Whereas researchers using CTT reliability use principal component analysis and FA to select items from a preliminary item set into the final test or questionnaire and then estimate reliability, researchers using the FA approach to reliability estimate a confirmatory factor model and a reliability measure tailored to the instrument's factor structure. The item set may be adapted based on the goodness-of-fit of the FA model to the data. Items having small loadings on each factor or cross loadings across factors are often candidates for removal, a strategy also used in CTT-based instrument construction. In FA reliability estimation, the true-score variance is modeled by latent variables that replace the true score. In this section, we discuss two factor models resulting in several reliability methods for test score X .

Methods

One-Factor Model. For one item and one latent variable, [Bollen \(1989, pp. 218–221\)](#) discussed the next model, dropping latent-variable index m ,

$$X_j = b_j + a_j\xi + \delta_j.$$

This model is also known as the model for congeneric measures ([Jöreskog, 1971](#)). Residual δ_j consists of two components, which are a unique error U_j typical of item j , and random measurement error consistent with CTT, resulting in $\delta_j = U_j + E_j$. The unique error U_j has unknown variance, $\sigma_{U_j}^2$, and thus cannot be separated from $\sigma_{E_j}^2$. Without going into further detail and consistent with the practice of FA reliability estimation, we assume $\delta_j = E_j$, implying that residual variance is random measurement error variance. The one-factor model thus equals

$$X_j = b_j + a_j\xi + E_j,$$

with CTT true score modeled as

$$T_j = b_j + a_j\xi.$$

Thus, in the FA reliability approach, the true score depends on latent variable ξ , which is a quantity the different items in the test have in common, and the item parameters b_j (intercept, difficulty) and a_j (loading on the latent variable). CTT defines the true score of an item as the expected item score across independent repetitions. The item true score depends on the item only, but different items may measure unrelated attributes or unrelated sets of attributes. This is what the model represents mathematically, but not what a test constructor will pursue. Instead, the test constructor will select items to assess the attribute of interest as well as possible, based both on theoretical and statistical analysis, but this does not affect the fact that CTT does not model the true score and estimates test-score reliability irrespective of the dimensional composition of the item set. This is the fundamental difference with the FA approach to reliability.

Based on the classical definition of reliability, we define ([Bollen, 1989, p. 220](#)) the reliability of test score X as in the one-factor model (OFM) as

$$\rho_{XX'}^{\text{OFM}} = \frac{\sigma_T^2}{\sigma_X^2} = \frac{\sigma^2(b_j + a_j\xi)}{\sigma^2(b_j + a_j\xi) + \sigma_E^2}.$$

Under particular restrictions not further discussed, the variance $\sigma^2(b_j + a_j\xi)$ can be estimated using the squared sum of the factor loadings $(\sum_{j=1}^J a_j)^2$ and variance σ_E^2 can be estimated using the sum of the items' residual variances. The result is coefficient ω ([McDonald, 1999; Revelle and Zinbarg, 2009](#)). The right-hand side of the definition represents the one-factor model reliability, which we have equated to the CTT reliability on the left-hand side. However, equality will hold only if the one-factor model perfectly fits the data for a real test or questionnaire, a situation that will not hold in the practice of test and questionnaire construction. Notation $\rho_{XX'}^{\text{OFM}}$ represents the former situation.

We already pointed out the opinion that coefficient α can only be used when the items satisfy the mathematical requirement of essential τ -equivalence, which is then interpreted as a one-factor model. This one-factor model is considered the FA interpretation of CTT. Rather than defining reliability for test score X , [Mellenbergh \(1994, 1998\)](#) studied reliability of the estimated latent-variable score rather than the test score as an estimate of the true score.

The model for congeneric measures is the point of departure in Mellenbergh's proposal. The model allows items to vary with respect to item parameters b_j and a_j , and population error variance, thus allowing $\sigma_{E_j}^2 \neq \sigma_{E_k}^2$ ([Bollen, 1989, p. 208](#)). Mellenbergh noticed that one can only estimate the item parameters b_j and a_j when the origin and unit of latent variable ξ are defined. This is done by means of standardization, such that in the population $\mathcal{E}(\xi) = 0$ and $\sigma_\xi^2 = 1$. We skip the detailed development of the model and follow [Mellenbergh \(1994\)](#) to define a reliability coefficient in which the variance of the latent variable, σ_ξ^2 , replaces the variance of the true score, σ_T^2 , and the variance of the estimated latent-variable score, $\hat{\xi}$, conditional upon latent-variable score

ξ , $\sigma_{\xi|\xi}^2$, also known as the residual variance, replaces error variance, σ_E^2 . The conditional variance of the estimated latent-variable score equals

$$\sigma_{\xi|\xi}^2 = \left(\sum_{j=1}^J \frac{a_j^2}{\sigma_{\varepsilon_j}^2} \right)^{-1}.$$

Following the definition of CTT reliability for test score X , the reliability of the estimated latent-variable score is defined as

$$\rho_{\xi}^{\text{OFM}} = \frac{\sigma_{\xi}^2}{\sigma_{\xi}^2 + \sigma_{\xi|\xi}^2}.$$

Because $\sigma_{\xi}^2 = 1$ by definition, reliability reduces to

$$\rho_{\xi}^{\text{OFM}} = \left[1 + \sigma_{\xi|\xi}^2 \right]^{-1}.$$

These are theoretical definitions, and simple methods exist for estimating latent-variable scores ξ and variance $\sigma_{\xi|\xi}^2$, thus allowing the estimation of reliability ρ_{ξ}^{OFM} (Mellenbergh, 1994, 1998). Raykov (1997, 2001) proposed the adaptation of coefficient α to congeneric measures. What matters here, is that adopting a factor model to replace CTT produces a new model different from CTT and has consequences for the reliability definition adopted. This consequence is important but it often is not recognized.

Multi-Factor Model. As we saw already, the multi-factor model (MFM) equals

$$X_j = b_j + \sum_{m=1}^M a_{jm} \xi_m + \delta_j.$$

Clearly, the MFM opens a wide range of possible models for the item scores, and to avoid trial and error it is advisable to depart from a well-founded attribute theory, if available. This limits candidate models to only a few the theory predicts. This approach implies fixing loadings for some items on some factors to 0, $a_{jm} = 0$, when latent variable ξ_m is irrelevant for the response to item j . In the ideal case, one tests whether a set of hypothesized loadings produces a fitting model, but we do not know examples of this scenario.

A simple MFM assumes that each item loads on at least one latent variable and that at least two items load on the same latent variable, so that the model does not allow unique components. In FA reliability, one usually assumes intercept $b_j = 0$, so that the true score relates to the factor model by

$$T_j = \sum_{m=1}^M a_{jm} \xi_m.$$

The test score is written as

$$X = \sum_{j=1}^J X_j = \sum_{j=1}^J \sum_{m=1}^M a_{jm} \xi_m + \sum_{j=1}^J E_j.$$

Reliability of test score X for the MFM is defined as (Raykov and Shrout, 2002)

$$\rho_{XX'}^{\text{MFM}} = \frac{\sigma_T^2}{\sigma_X^2} = \frac{\sigma^2 \left(\sum_j \sum_m a_{jm} \xi_m \right)}{\sigma^2 \left(\sum_j \sum_m a_{jm} \xi_m \right) + \sigma_E^2}.$$

Only if the factor model fits the data well does $\rho_{XX'}^{\text{MFM}}$ equal CTT reliability. In practice, ignoring relevant latent variables or including irrelevant latent variables, incorrectly specifying the loading structure, or a combination of these errors, leads to a misfitting factor model and a biased estimate of reliability $\rho_{XX'}$.

Revelle and Zinbarg (2009) rephrased $\rho_{XX'}^{\text{MFM}}$ as follows. Let the item communality be denoted h_j^2 . This is the proportion of variance of item score, X_j , explained by the common latent variable and the group variables, which are factors on which subsets of items load but not all items. Let M relevant latent variables be orthogonal or uncorrelated; then,

$$h_j^2 = \sum_{m=1}^M a_{jm}^2.$$

The complement of item communality h_j^2 , denoted d_j^2 , is the proportion of unexplained or residual variance, so that $d_j^2 = 1 - h_j^2$. The complement approximates the item's proportion of error variance. For standardized item scores, coefficient ω_t is defined as (McDonald, 1999; Revelle and Zinbarg, 2009)

$$\omega_t = 1 - \frac{\sum_j (1 - h_j^2)}{\sigma_X^2} = 1 - \frac{\sum_j d_j^2}{\sigma_X^2}.$$

In CTT reliability, σ_E^2 replaces numerator $\sum_j d_j^2$, but because the models underlying the two equations are different, equating the coefficient ω_t to the classical reliability definition might be misleading.

The bi-factor model is a popular multi-factor model for which we briefly discuss the FA approach to reliability. The model defines a group factor for subsets of items and a common factor for all items. Thus, residual d_j in coefficient ω_t includes the variance explained by the common factor and the group factor for item j . Another method known as coefficient ω_h quantifies the degree to which the item set measures the common factor in a bi-factor model (e.g., Flora, 2020; Zinbarg et al., 2005). Raykov and Shrout (2002) estimated coefficient ω by means of a structural equation modeling approach. Pfadt et al. (2021) discussed a Bayesian approach to estimating the ω coefficient for the one-factor model, and Pfadt and Sijtsma (in press) studied the statistical properties of several ω coefficients.

Real-data example, continued

For the same data as analyzed in the section on CTT, we found estimate $\hat{\omega}$ based on one factor equal to 0.547, almost equal to CTT estimates $\hat{\alpha}$ and $\hat{\lambda}_2$. Given the messy factor structure we identified, we refrained from estimating variations of coefficient ω for the multifactor case.

Measurement precision

FA approaches to measurement precision are rare, a circumstance that could be explained from the focus of FA approaches on research rather than the diagnosis of individual behavior. Recently, Martin and Rast (2022) proposed an FA-based approach to modeling measurement precision which they called case-specific reliability, applicable to subgroups and covariates in addition to individual scores. Their approach estimates a non-linear, nonmonotonic function for reliability conditional on the latent variable, thus providing a function analogous to the test information functions in IRT we discuss shortly.

Comments

Whereas CTT and GT focus on error sources in test performance, estimate the magnitude of their influence on reliability, and aim at reducing this influence thus increasing reliability, the FA approach to reliability focuses on the factorial composition of the test data and defines reliability as the proportion of variance the common factor explains in the data. This proportion equals CTT reliability when the FA model fits the data, and then the common-factor variance equals the true-score variance. Given that FA models fit the data by approximation at best, an FA reliability method does not estimate reliability without bias, an observation that is true for all approaches to reliability.

The FA approach to reliability models the true score, and this is often seen as an advantage of the approach. However, the finding that a factor model fits the data by approximation does not imply that the item set measures the attribute of interest, unless a well-founded theory of the attribute laid at the foundation of the test construction. CTT and GT do not model the true score. This places the establishment of validity separate from estimating reliability. Reliability approaches modeling test performance using latent variables are faced with the same task.

Item response theory

Test design

Tests and questionnaires can be fixed as in the CTT, GT, and FA context, but a special feature of IRT is that its models allow different examinees to respond to different sets of items taken from large item collections known as item banks. These examinee-tailored tests allow the optimally precise measurement of the attribute of interest. This feature makes IRT reliability and measurement precision stand out from the other three approaches.

Model

FA is a linear latent-variable model for continuous dependent variables, and IRT is a non-linear model for discrete dependent or response variables. These response variables are dichotomous (e.g., correct/incorrect) or polytomous (e.g., ordered rating-scale

scores), and are transformed to response probabilities as functions of the latent variable (the factor in FA) and latent item characteristics. Like FA, one or more latent variables representing attributes model the relationship among the items. The number of IRT models is large (e.g., [Sijtsma and Van der Ark, 2021](#); [Van der Linden, 2016](#)). Therefore, we use general notation for the functional relation, denoted f , between a response probability for an item, P , and latent variables, θ , and item properties such as difficulty (comparable to the intercept in FA), and item discrimination (comparable to the item loading), quantified by parameters in η . For two items j and k , the response functions, which are usually assumed to be increasing, are

$$P(X_j \geq x|\theta) = f(\theta; \eta_j) \text{ and } P(X_k \geq x|\theta) = f(\theta; \eta_k).$$

For scores 0/1, the response probabilities are $P(X_j = 1|\theta)$ and $P(X_k = 1|\theta)$. Given that tests are mostly constructed to measure one attribute, there is usually just one latent variable, so that $\theta = \theta$. Function f is often a normal ogive (cumulative normal) or a logistic function. Like FA, IRT provides a model for the relationship between items allegedly measuring the same attribute or attributes.

Methods

[Kim \(2012\)](#) defined two items as parallel if their response functions are equal. Several methods are available for estimating latent variable θ , resulting in estimate $\hat{\theta}_i$ for everyone taking the test. Expectation $\mathcal{E}(\hat{\theta}|\theta)$ is the expected value of estimate $\hat{\theta}$ for a particular scale value θ , comparable to the true score in CTT; hence, $\sigma^2_{\mathcal{E}(\hat{\theta}|\theta)}$ can be compared to CTT true-score variance, σ_T^2 . Variance $\sigma^2_{\hat{\theta}|\theta}$ is conditional estimation-error variance, and expectation $\mathcal{E}(\sigma^2_{\hat{\theta}|\theta})$ is comparable to error variance σ_E^2 assessed for the whole group.

Because estimate $\hat{\theta}$ is biased ([Lord, 1983](#)), one cannot simply assume all results from CTT to be valid in the IRT context. Recalling CTT equality $\rho_{XX'} = \rho_{TX}^2$, biasedness of $\hat{\theta}$ implies that a similar equality in IRT does not hold ([Kim, 2012](#)). Two parallel tests result in estimates $\hat{\theta}$ and $\hat{\theta}'$. Item parameters η_j have been estimated previously with enough precision and are assumed known. Based on [Lord \(1980, p. 52\)](#), [Kim \(2012\)](#) defines reliability of parallel measures as

$$\rho_{\hat{\theta}\hat{\theta}'} = \frac{\sigma^2_{\mathcal{E}(\hat{\theta}|\theta)}}{\sigma_{\hat{\theta}}^2} = 1 - \frac{\mathcal{E}(\sigma^2_{\hat{\theta}|\theta})}{\sigma_{\hat{\theta}}^2}.$$

In general, because of biasedness in $\hat{\theta}$, we have that $\rho_{\hat{\theta}\hat{\theta}'} \neq \rho_{\hat{\theta}}^2$. See [Holland and Hoskens \(2003\)](#) for further relationships between CTT and IRT.

Real-data example, continued

Estimates of reliability in an IRT analysis are rarely encountered in research reports because the focus in IRT is on the Fisher information function ([Sijtsma and Van der Ark, 2021](#), chap. 4). As an illustration for this entry, we obtained a CTT-like reliability for the data used in the CTT section by replacing the true-score variance with the variance of the estimated latent variable $\hat{\theta}$ from the unidimensional two-parameters logistic model and the error-score variance with the sample mean of the squared standard errors of the estimates $\hat{\theta}_i$ across the various $\hat{\theta}_i$ values ([Chalmers, 2012](#)). To maintain comparability with the CTT and FA estimates, we ignored the multidimensional data structure and refrained from a goodness-of-fit analysis common to an IRT data analysis. Using the R package *mirt* ([Chalmers, 2012](#)), we obtained estimate $\rho_{\hat{\theta}\hat{\theta}'} = 0.620$. This value is almost equal to $\hat{\lambda}_4$ for the 5th percentile [Hunt and Bentler \(2015\)](#) proposed, but this may be coincidental.

Measurement precision

Reliability never played a major role in IRT because the availability of the Fisher information function, which equals the inverse of the standard error of estimate $\hat{\theta}$ conditional on θ , denoted $\sigma_{\hat{\theta}|\theta}$, made it superfluous. The information function and its inverse can be estimated for the J items and each of the individual items. Conditional standard error $\sigma_{\hat{\theta}|\theta}$ is the IRT analogy of the standard error of measurement in CTT and has the advantage that it depends on the scale of θ . The standard error thus shows for item j where it measures most precise on the θ scale, and items can be selected such that the resulting test has measurement precision where it is most useful. An example is a cut score θ_c for selecting students for a follow-up program, where precision at the cut score is mandatory and items are selected that optimize precision at θ_c . In intelligence testing, one may require equal precision along the whole scale and items that provide measurement precision at levels varying from low to high covering the whole scale range.

A feature of IRT is the possibility to tailor a test to an individual's unknown θ value in a search process, which starts with a few "average" items, estimates θ_i , then based on $\hat{\theta}_i$ selects the next item, updates the estimate of θ_i , selects the next items, and so on until $\sigma_{\hat{\theta}|\theta}$ is considered small enough for the measurement's purpose. This procedure is known as tailored or adaptive testing. It can only

work well when for the attribute of interest, the researcher has access to a large item bank of which the items have been pretested in large samples, so that their parameter estimates are known with enough precision to consider them the true parameter values.

Comments

From the advent of IRT in the 1950s, reliability never played an important role and attention soon was directed at the information function and the conditional standard error. The availability of the information function undeniably has great advantages for constructing tests. Like the FA approach, the IRT approach to reliability is based on latent variables, whereas CTT and GT approaches deal with observable variables. A wide variety of methods allows the estimation of reliability of observable test scores and latent variables, but the question whether the test measures the attribute of interest requires an independent study.

Conclusion

We discussed the four main approaches to reliability discussed in the psychometric literature. CTT is a random measurement-error theory that does not model the true score. In this sense, CTT makes abundantly clear that the question whether the test measures the attribute of interest well must be answered separately from a reliability analysis by means of a validity study. Reliability concerns the issue whether the measurement is repeatable, and validity addresses the question whether the test measures the attribute of interest. Whereas CTT focuses on a single test administered to a well-defined population under standardized conditions, GT separates person measurement from situational influences the test constructor wishes to control when they have a confounding effect on the person measurement. Getting these sources, such as test length and performance raters, under control means estimating the variance components in the test scores they represent and assessing the numbers of items and raters needed to reduce their confounding influence on person measurement. GT does not criticize CTT and is not at odds with CTT but generalizes it to obtain better control over testing conditions considered relevant.

The FA approach to reliability models the true score by means of a factor model, introducing a distinction between wanted and unwanted factors, the latter sometimes referred to as systematic error sources. Reliability is limited to wanted factors, often a factor common to the items. Whereas FA is a linear model that assumes continuous item scores modeled by one or more factors, IRT is a non-linear model for discrete item scores dependent upon one or more latent variables playing the same role in IRT as factors do in FA. Compared to CTT and GT, FA and IRT posit a particular structure on the items and the relationship between the items. Whether this is useful depends on the goodness-of-fit of the hypothesized FA and IRT models, and whether the fit is good depends on the strength of the theory about the attribute underlying the construction of the measurement instrument. As with CTT and GT, validity research is key to useful measurement giving it its meaning, and reliability expresses the precision of person measurement given the model on which it is based.

Validity is at the core of all aspects of testing from enumerating the intended score interpretations and uses of the test to evaluating the consequences of intended and actual test use. Validity refers to the extent to which evidence supports or refutes intended and actual test score interpretations and uses as well as resulting consequences. Validation is the systematic process of obtaining and evaluating this evidence. We argue that validity must be addressed throughout the testing process, beginning with defining the construct to be assessed. A construct refers to the knowledge, cognitive skills and strategies, and other attributes to be assessed.

We advocate the argument-based approach to validity because it provides a framework for articulating intended score interpretations and test uses as well as their consequences, both intended positive consequences and potentially unintended negative consequences, and for identifying the body of evidence needed to support score interpretations and uses of tests. Such a framework also allows for the articulation and evaluation of potential alternative explanations. The validity of score interpretations and test use rests on intentional test design that is responsive to different groups in the targeted population. Such groups typically are defined by ethnicity, race, culture, language dominance, disability, economic status, and other relevant experiential, social, and personal characteristics. To address fairness and equity issues in testing an essential aspect of the argument-based approach to validity are logical and empirical evaluations of the validity of score meaning and test use for different groups in the targeted population.

In this article, we begin with a brief discussion on the inherent relationship between validity and fairness. We agree with others that fairness investigations are validity investigations. Following this, we discuss the argument-based approach to validity, including how principled approaches to test design and theories of actions can support the interpretation and use argument and the validity argument. As an illustration, we lay out an interpretation and use argument and a validity argument for a particular use case. We then discuss the central role of the consequences of test use in the argument-based approach.

Fairness as validity

We adopt the prevailing view that fairness in testing is essential to the validity of score interpretation and test use, and concerns with fairness must be addressed throughout the testing process, from defining and labeling the construct, to designing, developing, administering, and scoring the test, to interpreting scores and evaluating test use and their consequences. Validity theorists have forwarded the view that fairness investigations are validity investigations. Messick (1998) advocated that beliefs and values bear on fairness evaluations of testing programs and he considered validity and fairness appraisals akin to value judgments. Kane (2012) furthered this view by indicating that fairness and validity investigations are similar ways of examining the same question: “Are the proposed interpretations and uses of the test scores appropriate for a population over some range

of contexts" (p. 177). Fairness investigations have emphasized the comparability of score interpretations, appropriateness of rules used to make decisions, and comparability of consequences across groups (Kane, 2010) however we contend that fairness investigations must begin with an examination of how the construct of interest is defined and by whom. These fundamental fairness investigations fall within the realm of validity. The *Standards for Educational and Psychological Testing* (American Educational Research Association (AERA) et al., 2014) also views fairness as a fundamental validity issue that requires attention throughout the design and development of the test as well as when interpreting and using scores. We agree with this perspective that fairness investigations *are* validity investigations.

For assessments to support the validity and fairness of score meaning and test use, individuals, regardless of group affiliation, should have equitable opportunity to access the construct measured. This requires that validity and fairness investigations begin with an appraisal of the appropriateness of the conceptualization of the construct for different groups in the targeted population. It is not necessarily the targeted construct that is assessed, instead it is the individual's construction of knowledge and ways of knowing that arise from one's social, cultural, and personal experiences (Gordon and Rajagopalan, 2016; Hood, 1998; Messick, 1998; Nortvedt et al., 2020; Randall, 2021). The knowledge, skills, and other attributes evoked by examinees when responding to assessment tasks depend on the assessment context as well as the individual's cultural, linguistic, and experiential histories. Assessments, in particular educational assessments, that account for the different ways individuals know and express their understandings in their design and development have the potential to enhance the validity and fairness of score interpretations and test use (Trumbull and Nelson-Barber, 2019). Being responsive to different cultures in assessment design recognizes testing as a situated culture practice (Gordon and Rajagopalan, 2016; Hood, 1998). We and others argue that this calls for a critical appraisal of the values, beliefs, and assumptions held by those who mandate, design, develop, and use tests.

Linking values to validity and fairness

Decisions made in test design, development, and use rest on value judgments (Cronbach, 1976; Messick, 1989; Kane, 2006), and such judgments can affect the validity and fairness of score interpretations and test use for individuals with different cultural and linguistic backgrounds. Each step of the testing process rests on value judgements including the articulation of the intended purposes and uses of a test, the conceptualization of the construct, the design and development of tasks and scoring procedures, the development of performance level descriptors, the development of performance standards for determining competency and certification, and the design of score reports and accompanying interpretive guides. Value judgments also underlie the identification of the intended positive consequences and the potential unintended, negative consequences.

Attention to differing values can uncover fairness and equity issues in the design, development, and use of tests for individuals from different backgrounds. As an example, consider the case of using a test for decisions regarding high school graduation. Although its intended consequence of raising standards and improving learning for all students is worthy, such use has had a differential effect on students who traditionally have been underserved. Judgments regarding whether the benefit of using tests in graduation decisions to raise standards outweigh their undesirable effect on different groups of students depends on the beliefs, values, and assumptions held by different stakeholders (Lane, 2020).

Threats to validity and fairness

Two sources of potential threats to the validity of score interpretations and uses are construct underrepresentation and construct-irrelevant variance (Messick, 1989). Construct underrepresentation occurs when the assessment does not capture important facets of the targeted construct. The extent to which the assessment is too narrow or underrepresents the construct will impact the generalizability of score inferences to the broader construct domain. As an example, if a science inquiry assessment does not full represent inquiry skills as laid out in the construct definition for the test, generalizing performance on the assessment to the full range of those inquiry skills is jeopardized.

Construct-irrelevant variance occurs when the assessment measures one or more constructs that are irrelevant to the targeted construct in addition to measuring the targeted construct. Construct-irrelevant variance may differentially impact the performance of different groups of individuals. As an example, a mathematics assessment which has a substantial reading load may depress the performance of learners whose primary language is not the tested language. These two threats to validity play an essential role in the appraisal of the validity and fairness of score interpretations and test use.

Argument-based approach to validity

The argument-based approach to validity has been widely recognized for evaluating score interpretations and test use (Cronbach, 1971, 1988; Kane, 1992, 2006, 2013; Shepard, 1993). The concept of an argument-based approach to validity can be traced to the seminal article by Cronbach and Meehl (1955) where they discuss how validation involves defending a proposed interpretation of test scores. Later, Cronbach (1988) extended his thinking regarding the argument-based approach to validity by acknowledging the importance of linking social and personal consequences and values in the argument.

Kane (2006) expanded on the argument-based approach to validity by specifying an interpretive argument and a validity argument. To emphasize a focus on the validity of test use as well as score interpretation, Kane (2013) shifted from using the term

“interpretive argument” to “interpretation and use argument”, although it should be noted that he emphasized test use in the interpretive argument. The interpretation and use argument (IUA) explicitly links the inferences from test performance to decisions and uses, including the actions resulting from the decisions and uses. Consequences of test decisions and uses therefore are integral to the argument-based approach to validity. The validity argument provides a comprehensive framework, including the rationales, assumptions, and backing or evidence, to help support or refute the inferences and uses specified in the IUA. The IUA guides all aspects of the testing process, including test design and use, provides the foundation for validation, and is critically evaluated against plausible alternative interpretations and uses (Kane, 2004).

The validity argument entails obtaining both logical and empirical evidence to evaluate the soundness of the claims and underlying assumptions in the IUA. As the backing for the IUA, the validity argument involves an overall evaluation of the appropriateness of the proposed score interpretations and test uses by providing a coherent analysis of the evidence for and against proposed score interpretations and uses (AERA et al., 2014; Cronbach, 1988; Kane, 1992, 2006, 2013). The validity of a score interpretation and use depends on the strength of the chain of evidence leading from making inferences from the task to performance to the inferences and uses of the scores and their resulting consequences. Shepard (1993) succinctly stated that the validity argument frames the questions:

What does the testing practice claim to do? What are the arguments and the intended aims of the test? What does the test do in the system other than what it claims, for good or bad? (p. 429).

Cronbach (1998) reminds us that when articulating a validity argument, one needs to play the “devil’s advocate” (p. 5) by identifying competing or rival hypotheses about score interpretations and uses. The argument-based approach provides a practical approach to validation by specifying the inferences and assumptions for appraisal and allows for prioritizing the forms of evidence needed in terms of the most pertinent inferences of the argument that require support (Kane, 1992, 2004).

Inferences in the IUA

The IUA consists of inferences connecting the observed test performance to the conclusions of interest. Inferences relevant to most IUAs are the scoring, generalization, extrapolation, and decision/use inferences proposed by Kane (2006, 2013). However, every IUA does not need to address every inference, but every IUA should include the most critical inferences. As a presumptive argument, Kane (2006, 2013) illustrated the IUA and its inferences using Toulmin’s (1958) model for presumptive inferences. As Kane (2006, 2013) describes, each inference goes from a data point to a claim. The inference employs a warrant which is a general rule for making claims based on data and this warrant is based on assumptions. The backing, or evidence, provides support for the warrant and its assumptions or it might refute the warrant and its assumptions.

The scoring inference links the observed performance of an examinee to a score by a scoring procedure developed during test design. The warrant is that a scoring rule assigns a score to the test performance accurately and consistently. The generalization inference refers to generalizing the examinee’s score over various measurement conditions such as items, occasions, and raters. The observed score is an estimate of the universe score and score interpretations are “extended from a claim about observed performances to a claim about expected performances over the universe of generalization” (Kane, 2016, p. 25). The extrapolation inference extends the claims of examinees’ observed scores to their performance in “real-world” scenarios. The warrant is that examinees who can apply their knowledge and skills to the assessment tasks can apply those knowledge and skills in the real world. The decision/use inference involves making decisions, such as selection, placement, certification, and proficiency decisions, based on the examinee’s observed score. The warrant is a rule for how the decision will be made. Evaluating decisions about individual and aggregate scores involves appraisal of both intended and unintended consequences.

In addition to these inferences in the interpretive chain, we propose the “performance inference” that would occur prior to the scoring inference, providing a link from the task to the performance. The claim would be that the task elicits the intended knowledge and skills, and the assessment is representative of the defined construct. The performance inference positions the conceptualization of the construct and the design and development of the assessment at the forefront of the IUA and validity argument. In their applications of the IUA, Chapelle et al. (2007, 2010) include domain description prior to the scoring inference and similarly, Shaw et al. (2012) include construct representation. The evaluation of the construct representation of tasks in terms of knowledge, skills, and other relevant attributes as well as principled approaches to test design provide backing, or evidence, for the performance inference. The performance inference explicitly links the IUA and validity argument to assessment design and development.

Enacted interpretations and uses

The interpretation and use of scores in practice may be quite different from the intended interpretations and uses. Consequently, it is insufficient to evaluate only the intended interpretation and uses of test scores, the actual or enacted interpretations and uses must be part of the IUA and validity argument (Coburn and Turner, 2011; Moss, 2013, 2016; O’Leary et al., 2017). The enacted interpretations and uses are more diverse and complex than the intended interpretations and uses (Coburn and

Turner, 2011; Moss, 2013, 2016), and may result in undesirable consequences for some individuals or groups. Test use varies depending on the context and needs of those who are using the tests, and these uses and needs, including local uses and needs, as well as their consequences require an evaluation in terms of their appropriateness and potential negative impact on individuals and groups.

Principled approaches in test design to support the IUA

Principled approaches to test design, such as Evidence Centered Design (ECD) (Mislevy et al., 2003), provide a framework for articulating the knowledge, skills and other attributes needed for successful task performance. As an example, within the ECD framework, evidence observed in examinee performance on tasks is used to support claims about individual's knowledge and skills. An explicit delineation of the claims and evidence to support these claims can help minimize construct-irrelevant variance and help ensure appropriate representation of the targeted knowledge and skills. Such principled approaches to assessment design provide validity evidence for evaluating score meaning and use.

The use of principled approaches to test design in conjunction with universal design principles provides a mechanism to make assessments responsive to different cultural, linguistic, and educational groups. Universal design principles for learning include the need for multiple means of representation, multiple means of action and expression, and multiple means of engagement (Thompson et al., 2002). The application of these universal design principles to test design, development, and administration recognizes that individuals from different cultural, linguistic, and educational backgrounds may have different ways of knowing and understanding and different ways of demonstrating their knowing and understanding. The application of universal design principles throughout every phase of test design, development, and implementation affords accessible assessments by minimizing construct-irrelevant barriers that may impede test performance.

Sources of validity evidence

The 2014 *Standards* provide five sources of evidence, evidence based on test content, response processes, internal structure, relations to other variables, and consequences of testing.¹ These five forms of validity evidence can be used to inform our thinking when designing validity investigations. Some researchers (Sireci, 2013; Zumbo and Chan, 2014) have suggested to use these sources of validity evidence as a framework for validation research, however others believe they are insufficient and lead to inadequate validation programs (Chapelle, 2011; Newton, 2016). As an example, Chapelle (2011) argued for examining the inferences in the argument instead of consulting a list of sources of validity evidence. We and others contend that the IUA provides a more comprehensive framework for validation by linking intended inferences and uses to evidence as well as linking plausible alternative inferences and uses to evidence (Lane and Marion, in press). The five sources of evidence proposed by the *Standards* in addition to other sources of evidence however can be encompassed within IUA and validity arguments.

IUA and validity argument use case

To illustrate the inferences in an IUA consider an assessment system used to examine the proficiency of students in disciplines such as mathematics, science, civics, history, and language arts. The assessment system includes performance tasks that are designed locally as well as performance tasks that are designed at the state or country level, and these performance tasks are administered at instructionally appropriate times throughout the year.² Such a performance assessment system provides an opportunity for teachers, culture experts, measurement professionals, and other relevant experts to collaboratively develop local performance tasks and scoring rubrics that reflect how students come to know and understand content within their own culture while adhering to rigorous content standards. A goal of this type of assessment system is that it leads to more valid score interpretations and uses.

For this use case, we provide a description of the inferences, some underlying assumptions, and evidence to support these assumptions. Of course, there may be other inferences and assumptions dependent on the specific use case. We also address the need to provide evidence in support of the inferences for different groups in the targeted population. For example, the response processes evoked by the assessment should be similar across different groups, the scoring of the performances should not bias one group over another, the generalizability of the inferences across groups should be comparable, and the consequences of the uses of the assessment should not inappropriately favor one group over another.

¹The 2014 *Standards* used the phrase "evidence for validity and consequences of testing" as if to separate validity from consequential evidence. The *Standards* also links validity "to interpretation of test scores for proposed uses of tests" (p. 11). As expressed by Lane and her colleagues (Lane and Niepokoj, 2018, Lane and Marion, in press), although the *Standards* offers much needed advice on validation efforts, it provides a narrow view of validity, stating that validity refers to score interpretations "for proposed uses" instead of explicitly stating "and their uses". The *Standards* also provides an ambiguous view on whether the use of tests and their consequences are part of the IUA and validity argument.

²This proposed performance assessment case draws on features of the Performance Assessment of Competency-Based Education (PACE) pilot initiative (New Hampshire Department of Education, 2016) that consists of a combination of locally developed performance tasks and common performance tasks shared by participating districts with a smaller statewide assessment component.

Performance inference

The performance inference links the tasks to the student performance. For this use case, the underlying assumption is that the tasks elicit the intended knowledge and skills and the assessment represents the intended construct for all students. Evidence to support this assumption includes, but is not limited to, the following:

1. Documentation specifying how the construct was conceptualized and defined and what groups were involved in defining the construct. (Content standards may be used to define the construct.)
2. Documentation specifying how principled approaches were used in designing the assessment tasks and rubrics, including the use of cognitive, socio-cognitive, and sociocultural theories of learning.
3. Examinee response evidence such as think alouds for different cultural and linguistic groups to evaluate whether the intended knowledge and skills are evoked.
4. Content and cultural expert review of the tasks and rubrics.
5. Alignment studies that evaluate the link among the defined construct (e.g., content standards), assessment specifications, and assessment tasks.

As an example, asking students to think aloud as they perform the task as well as evaluating any written responses to evaluate the knowledge, skills, and strategies evoked by the students provides backing or evidence to support or refute the performance inference.

Scoring inference

The scoring inference links the performance to the score. Pertinent assumptions underlying the scoring inference for this use case is that (1) rubrics capture the intended knowledge and skills and account for different ways of expressing those knowledge and skills, (2) raters appropriately internalize the rubric criteria and apply them accurately, and (3) tasks are administered appropriately. Evidence to support these assumptions includes the following:

1. Documentation of the design of the scoring rubrics and weighting of the criteria to produce scores.
2. Evaluation of the accuracy and consistency of implementation of the rubrics by the teachers, including an evaluation for responses from different groups of individuals.
3. Evidence of the appropriate administration of the performance tasks.
4. Audit of the scores assigned by the teachers.
5. Evaluation of the comparability of scores from locally developed tasks and state/country developed tasks.
6. Evaluation of the validity/comparability of score meaning across different groups of individuals.

An evaluation of the accuracy and consistency of the implementation of the rubrics may include rater think alouds to examine whether raters are interpreting and applying the rubric criteria to the responses appropriately. It may also involve having more than one teacher in a locale score a subset of the responses to the task. An audit of the teacher ratings may involve a random sample of performance tasks from a random sample of teachers to be scored by trained raters designated by the state. A systematic evaluation of the comparability of the scores from locally developed tasks and state developed tasks may also shed light on the accuracy of local scoring and the rigor of locally developed tasks. The comparability of scores in this assessment scenario however may be reduced to some extent in favor of using tasks that are more culturally and instructionally responsive.

Generalization inference

The generalization inference links the score to the broader construct or domain. Generalizability studies (Cronbach et al., 1972) that examine the generalizability of the scores over tasks, raters, and other relevant measurement conditions provide evidence to evaluate the generalization inference. An assumption is that students should be able to generalize their knowledge and skills to other tasks within the domain. Evidence to support the assumption underlying the generalization inference includes the following.

1. Generalizability studies for tasks, raters, and other relevant measurement conditions.
2. Evidence to support the generalizability of scores across groups.
3. Studies of the internal structure of the assessment across groups to lend support for reporting one or more scores as intended.

As an example, a multi-group factor analysis provides evidence of whether the structure holds across relevant groups. The generalization inference may be threatened if the performance assessment consists of a relatively small number of tasks, but in this use case the performance tasks may better represent the construct domain because they are implemented throughout the instructional year, leading to a broader range of tasks.

Extrapolation inference

The extrapolation inference links the test performance to the expected performance in real-world contexts. Because performance assessments intend to assess students at a deeper, more critical-thinking level, extrapolating to the real-world context may be less of an issue than with other forms of assessments. Evidence to support the assumption that student performance on the assessment is similar to their performance in the real world includes the following.

1. Expert review of the alignment of knowledge and skills assessed to the knowledge and skills used in diverse real-world contexts and communities.
2. Expected relationships between assessment scores and scores from other criterion measures hold and are similar across different groups.

Because a goal of the locally developed tasks is to design them to be more relevant to cultural groups, an examination of whether they do reflect the way students construct, organize, and display knowledge and skills in their own communities would support this goal.

Decision/use inference

The decision/use inference links the score to the decisions, uses, and resulting consequences. The assumptions underlying the decision/use inference for this use case includes (1) assignment to performance levels is appropriate, (2) uses of test results are appropriate, and (3) positive consequences are maximized while negative consequences are minimized. Evidence to support the assumptions underlying the decision/use inference includes the following.

1. Standard setting method and procedures are appropriate.
2. Decision consistency and accuracy is appropriate and similar across groups.
3. Intended positive consequences are maximized while unintended negative consequences are minimized for all groups of individuals.

Standard setting evidence includes an evaluation of whether the standard setting procedures result in reasonable performance standards and whether potential adverse impact was considered. Performance assessments have been used as levers of educational change, so an evaluation of the consequences is essential, such as whether instruction and learning for all students has benefited because of the use of performance assessments (Lane, 2014, 2020).

This use case which specifies the inferences, assumptions, and the evidence to support them requires tailoring to specific assessment purposes and contexts. It highlights the most pertinent assumptions and evidence, but it is not exhaustive. A goal of ours was also to address fairness and equity issues in laying out the IUA and validity argument. We acknowledge however that additional validity and fairness evidence to support score meaning and use for different groups would strengthen the IUA and validity argument.

Other IUAs and validity arguments have been developed for different types of assessments. As an example, Kane and his colleagues (Kane, 2004; Kane et al., 2017) illustrated a general IUA for credentialing testing programs that delineates associated warrants, assumptions, and evidence for the assumptions. Lane and Marion (in press) propose a general IUA and validity argument for the design of more culturally responsive and sustainable educational assessments.

Theories of action to support the IUA

Theories of action provide a framework for the IUA and validity argument by identifying critical testing components and their logical points of impact. A theory of action for an assessment system should include the rationale for the use of the assessment, the mechanisms that will lead to the intended outcomes, and the intended and potentially unintended outcomes or consequences. Bennett (2010) indicated that the theory of action for an assessment system provides a framework for bringing together score meaning and impact claims, with an emphasis on claims about the intended consequences of the assessment system for both individuals and institutions. In describing the theory of action for the Cognitively Based Assessment of, for and as Learning (CBAL) initiative, Bennet (2010) illustrated how the assessment processes and mechanisms connect the design of the assessment with the intended outcomes and potential unintended outcomes, emphasizing the effects of the assessment system on individuals and institutions as well as the mechanisms behind the effects.

Alternate perspectives on the meaning of validity

Although the conceptualization of validity as pertaining to the appropriateness of test score interpretations and uses, as well as resulting consequences has been widely received some still adhere to more restricted conceptualizations of validity (Borsboom et al., 2004; Cizek, 2012). Borsboom et al. (2004) indicated that “a test is valid for measuring an attribute if and only if: (a) the attribute exists; and (b) variations in the attribute causally produce variations in the outcomes of the measurement procedure” (1061). This view links validity to a causal explanation, implying that changes in the tested attribute cause changes in the item responses, and that validation does not apply to score use. We argue that such restrictive views are limited because they do not consider test use and their consequences as integral aspects of the IUA and validity argument.

Consequences: an essential aspect of IUA and validity arguments

We adopt the view that the appropriateness of test-based decisions and uses is central to validity and therefore validity investigations must attend to consequences of score interpretations and test use, both the intended positive consequences and the potential

unintended negative consequences (Cronbach, 1971; Kane, 1992, 2006, 2013; Lane et al., 1998; Linn, 1997; Messick, 1989; Shepard, 1997). Five decades ago, Cronbach (1971) considered the appraisal of decisions and actions based on tests as part of validity evaluation and Messick (1983) made the role of consequences an inherent aspect of validity theory. In response to an ongoing debate regarding the inclusion of consequences of test use in validity investigations, Linn (1997) pushed for consequences to be integral to validity:

the best way of encouraging adequate consideration of major intended positive effects and plausible unintended negative effects of test use is to recognize the evaluation of such effects as a central aspect of test validation (p. 16).

In Messick's (1989) conceptualization of validity, he discussed the relationship of consequences with test use

Validity is an integrated evaluative judgment of the degree to which empirical evidence and theoretical rationales support the *adequacy and appropriateness of inferences and actions* based on test score and other modes of assessment (p. 13).

Messick's (1989, 1994) perspective on adverse social consequences as an aspect of validity however, limited them to being traced back to construct-irrelevant score variance or to construct underrepresentation. Unfortunately, the validity chapter in the *Standards* (2014) adopted this restricted view of the relationship between consequences and validity. We agree with Kane (2006) when he pressed that Messick's perspective gave consequences a secondary role in validation. Instead, like Kane and Cronbach (1971, 1988), we support the position that consequences have an essential role in the validity argument in that negative consequences could invalidate test use even if they cannot be traced to construct-irrelevant variance or construct underrepresentation. Cronbach (1988) pushed further indicating that those who mandate tests are obligated to evaluate whether a test use has "appropriate consequences for individuals and institutions, and especially to argue against adverse consequences" (p. 6). Consequences that may have adverse impact and systemic consequences are integral to the IUA and validity argument (Kane, 2013). Adverse social and personal consequences of testing bear on both validity and fairness issues.

In the context of language assessments, Bachman and his colleague (Bachman, 2005; Bachman and Parker, 2010) proposed an assessment use argument (AUA) that provides a framework for linking performance on assessments to decisions and use, laying out the intended consequences and the potentially unintended negative consequences. The AUA links score interpretations to decisions and consequences, specifying claims about outcomes, intended and actual interpretations, decisions, and consequences. Like Kane's IUA, the AUA positions the articulation of the intended positive consequences and potentially unintended consequences of test use at the beginning of the testing process. The warrant associated with consequences in the AUA states that "the *consequences* of using the assessment and making intended decisions will be beneficial to individuals, the program, company, institution, or system, or to society at large" (Bachman, 2005, p. 19). The AUA emphasizes not only intended but also *actual* interpretations, decisions, and consequences, broadening the need for appraisal to actual test use and their resulting consequences. As indicated by Bachman (2005), including consequences in the AUA positioned investigations of test consequences on instruction and learning as part of the AUA instead of them being external to the validity framework.

Consequences and tests as levers of educational change

The goal of test-based accountability systems in the US is to improve the educational opportunities provided to all students, narrow the achievement gaps, and prepare students for college and careers by holding schools, educators, and sometimes, students accountable. This section discusses validity issues with respect to the use of tests as levers of educational change in the US. It should be noted however that these validity issues are relevant to test-based accountability systems and the use of tests as policy levers in other countries. An early example was England's initiation of the 1862 "payment-by-results" policy which was implemented because of an increased demand for student enrollment in elementary schools (Stobart and Eggen, 2012). This policy required that teacher salaries reflect their student performance in reading, writing and mathematics which resulted in an instructional focus on drilling students in these subjects that lasted 30 years. The use of tests to serve as tools for educational reforms by policy makers requires evidence to support this intended use and resulting intended and actual consequences (Cronbach, 1982). There is an inherent conflict however in using tests for both instruction and accountability purposes as test design and development decisions differentially affect the validity of using the same test for these two purposes (Lane and DePascale, 2016).

The use of tests as policy levers bears on fairness and equity issues. Consequences of tests used in accountability systems typically have different impacts on different groups of students and in different schools and economic areas, and these differential impacts require evaluation as part of the validity argument (Lane and Stone, 2002). Differential test outcomes for students living in economically marginalized communities in the US, have led to undesirable consequences, including a narrowing of the curriculum and instruction and an increase in high school dropout rates. Evaluations of intended and actual test use in accountability systems need to establish whether the intended positive consequences are realized and whether potential unintended negative consequences are minimized. A systematic evaluation includes an appraisal of whether the test achieves its goals and the costs in attempting to achieve its goals.

Different stakeholders, including policymakers, advocacy groups, administrators, educators, parents, students, business leaders, and the community, have different, and sometimes conflicting, perspectives and values on the purposes and uses of tests as well as their consequences. While the stakeholders may change depending on the purpose of the test, the context for use, and the locale, differing values and perspectives need attention throughout the testing process. [Bachman \(2002\)](#) proposed the need for different IUAs that account for the conflicting values of different stakeholders which is likely impractical in many contexts. At the very least, the articulation of competing values from stakeholders will allow for a better understanding of the potential consequences, both positive and negative, of test use ([Lane, 2014, 2020](#)).

Evaluating the consequences of tests used as levers of educational change

Evaluating the effectiveness of tests used for accountability purposes requires attention to how well the tests are achieving their goals in terms of the motivation and practices of school administrators and educators and in terms of student achievement and learning ([Lane and Stone, 2002](#)). Those who mandate and use tests must make a case for the appropriateness of the decision rules in the use context, and consideration of whether any potential unintended negative consequences outweigh intended positive consequences prior to the use of a test as an instrument of policy. The articulation of intended and potential unintended consequences should occur in conjunction with the specification of the claims in the IUA. The validity argument should entail a systematic evaluation of how the testing achieves its goals and the cost of attempting to obtain its goals.

In previous research, a conceptual framework for evaluating consequences of assessment and accountability systems, both intended and unintended, was proposed ([Lane et al., 1998, 2002; Lane and Stone, 2002; Lane, 2020](#)). The framework provides a principled approach for evaluating consequences in the IUA and validity argument and can be modified for different purposes of educational assessments. We developed and implemented the framework to evaluate the consequences of the Maryland State Performance Assessment Program (MSPAP) which was comprised of performance tasks integrated across content disciplines. The goal of MSPAP was to promote performance-based instruction by providing opportunities for students to engage in problem solving and reasoning. The IUA addressed the intended consequences at multiple levels, individual, school, and state, by articulating a set of claims that required logical and empirical validity evidence at each level. It involved the specification of the forms of evidence to accumulate for both positive and potentially negative consequences for different participants, including students, teachers, and administrators, and at different levels, including state, district, school, class, and individual. To provide evidence of the assessment's effect on instruction, forms of evidence include surveys, focus groups, instructional logs, and a systematic evaluation of instructional tasks and assessments.

Using this framework to evaluate the consequences of MSPAP, *we found that teacher reported use of performance-based instruction accounted for differences in school performance on MSPAP in reading, writing, mathematics, and science. Schools that focused on performance-based instruction, such as the engagement of students in critical thinking and reasoning, had higher MSPAP scores than schools in which their instruction was less performance-based* ([Lane et al., 2002](#)). Another example of a performance-based assessment system and an examination of its impact is PACE (Performance Assessment of Competency-Based Education) which was an innovative assessment program for some districts in a state in the US. One assumption underlying the use of this performance-based assessment system, which was implemented throughout the school year, was that the knowledge and skills acquired by students in the PACE program would transfer to the statewide test that primarily consisted of selected-response items. Results from two studies provided evidence of this assumption in that for those students who participated in PACE there was not a negative impact on their statewide test scores ([Evans, 2019; Stone and Evans, 2021](#)).

When using test scores to make inferences regarding the quality of instruction, contextual information informs the inferences and resulting actions ([Haertel, 1999](#)). As an example, in the MSPAP study, we found that the percent of students receiving free or reduced lunch, which served as a proxy for socio-economic status, albeit an imperfect proxy, was not significantly related to school performance gains on MSPAP in mathematics, writing, science, and social studies ([Lane et al., 2002](#)). Although this can be conceived as a positive finding, some would argue that schools in economically disadvantaged areas should have shown greater gains because of their lower initial performance. The framework my colleagues and I developed stipulates the need for contextual information, such as socioeconomic status, funding per student, access to quality curriculum and materials, and stability of administrators, teachers, and students, to inform the evaluation of consequences. An understanding of contextual variables is critical for identifying barriers in achieving the intended outcomes.

Concluding remarks

In this article, we discussed how validity is central to every aspect of the testing process, from conceptualizing the targeted construct to evaluating the consequences of test use. Furthermore, fairness and equity issues are fundamental to the validity of score meaning and test use for individuals from different population groups. We and others contend that assessment design, development, and use should begin with an interpretation and use argument that explicitly links the inferences from the tasks to the decisions and uses, and to the resulting consequences. A validity argument then provides an evaluation of the claims and assumptions that are laid out in the IUA.

We maintain that values and beliefs affect the choices made when delineating the IUA and validity argument as well as when designing, developing, and using assessments. These values and beliefs must be understood and attended to because they bear

on the validity and fairness of score meaning and use for different groups of individuals. Educational testing programs that explicitly address how cultural, linguistic, and social experiences and practices shape how individuals learn, know, and demonstrate their understanding have the potential to lead to more equitable and valid test score interpretations, uses, and consequences.

Introduction

In 2016, a discussion about fairness might have begun with a general acknowledgment of the varied ways that fairness is understood in social, legal, and measurement contexts and then focus on issues specific to test design: “The goal of the fairness argument is to present evidence that the test is fair for various groups within the test-taking population” (Zieky, 2016, p. 96). Today, in the wake of the COVID-19 global pandemic beginning in 2019 and international Black Lives Matter demonstrations in 2020, conversations about fairness must take these global issues into account. Inattention to social context and justice is not an option anymore. Consequently, in this chapter, we acknowledge that fairness cannot be achieved without jointly considering inequity, anti-racism, and justice. The conventional definition of fairness offered in test design guides and professional standards seem woefully insufficient for a post-pandemic, anti-racist worldview. Fairness cannot be circumscribed solely to discussions of test design but should also include discussions of the processes used to make evaluative judgments of the meaning of test scores, the stakeholders involved in making them, the cultural and linguistic backgrounds of test takers, and the many ways test-based decisions have disadvantaged and continue to disadvantage subgroups. To this end, like Gipps and Stobart (2010), we take an inclusive view of educational assessment, including classroom and program assessment as well as high-stakes testing. We also see fairness as an ongoing project of justice (i.e., using assessment toward addressing injustice; Poe et al., 2018; Randall, 2021).

This entry has four sections. In the first section, we begin our discussion of fairness by presenting examples of (un)fairness in assessment systems used around the world and the types of challenges stakeholders and the public face in relation to addressing fairness considerations within those systems. Those examples inform the key terms we define in the second section. In our definitions, we include both terms used traditionally in measurement and newer terms. In the third section, we describe considerations on the future of fairness in measurement. The fourth section is the conclusion in which we provide a brief reflection on issues discussed in the article.

Setting the context: international examples of (un)fairness

Real-world examples, drawn from international contexts, such as Chile, the Middle East and North Africa, and the United States, demonstrate the difficulties of achieving fairness when resources are limited and tests are seen as barriers to accessing prestigious universities:

- On January 6 and 7, 2020, the Prueba de Selección Universitaria (PSU)—a battery of multiple-choice achievement tests taken by high school students applying for university admissions—was scheduled to be taken by approximately 300,000 applicants across Chile. Led by student organizations, the Coordinating Assembly of High-School Students, and the National Coordinator of High-School Students, protests erupted against the PSU. Protestors argued that the exams privilege wealthier students and increase economic inequality. Access to test centers were blocked and examination papers were burned. More than 27 people died, with thousands injured and arrested (Nugent, 2020). In October of 2021, large-scale demonstrations marked the anniversary of the protests (Cambero, 2021).
- On June 19, 2021, the Ministry of Education in Sudan ordered the nation’s internet service providers to shut down all mobile internet connections in advance of national secondary school examinations. In Algeria, the practice of shutting down the nation’s internet has occurred each year since 2016 during periods of national examinations. In Syria, the government stopped internet service across the country between May 31 and June 22 for approximately four and a half hours each day while students took their high-school examinations. And in Jordan, the government blocked the internet between June 24 and July 15, 2021, as students took their high-school examinations. Journalists noted that these practices violated United Nations Resolution 44/12 regarding internet shutdowns (Fatafta et al., 2021).
- On January 20, 2020, the Centers for Disease control confirmed the first case of COVID-19 in the US. By June 2022, more than one million people in the US had died of COVID 19 (Centers for Disease Control and Prevention, 2022a,b). The disease has had

a disproportionate effect on historically marginalized groups, resulting in huge disparities in hospitalizations and deaths (Centers for Disease Control and Prevention, 2022a,b; Lopez et al., 2021). The pandemic upended classroom teaching, forcing students from preschool to college age into online learning contexts. In US K-12 schooling, test scores in math and reading declined (Kuhfeld et al., 2022). In US higher education, the pandemic brought about many issues, including declines in student enrollment, declines in students' post-college labor outcomes, especially among students of color (Department of Education, 2021, p. 39, 41), and changes to admissions testing. By March of 2020, approximately 1000 of the 2300 private nonprofit and public bachelor's-granting colleges and universities offered students the option to apply without submitting standardized test scores. By October of 2020, nearly two-thirds of colleges and universities had adopted test-optional, or test score masked, policies in place (Conley and Masa, 2020). A February 2021 ACT survey of 4-year colleges found that 80% ended up being test-optional for the previous year and between 60 and 70% said they would likely remain test-optional or test blind post-COVID (ACT, 2021).

In terms of fairness, the PSU in Chile has been criticized for equity deficits in terms of economic inequality and opportunity to learn; in 2018, approximately 80,000 students did not have the opportunity to learn the material covered in the technical and professional section of the test—the educational track taken by the poorest in the nation. Politically, the PSU has come to symbolize a country divided between those desiring social change and those devoted to conservative policies; an October PSU anniversary demonstration, held in advance of November 2021 presidential and legislative elections, reveals the polarized nature of the country. Internet shutdowns in Middle East and North Africa have been framed as violating the United National General Assembly resolution “strongly condemning the use of Internet shutdowns to intentionally and arbitrarily prevent or disrupt access to or dissemination of information online” (United National General Assembly, 2020, p. 3)—an example of how educational testing and human rights are conflated when technology becomes a feature of the testing environment. In the US, the decline of standardized college admissions testing during the global COVID-19 pandemic strengthened the long-standing concerns that standardized admissions tests may not provide information on students that is sufficient to compensate for inequitable barriers to access created by the tests themselves. One early study of 100 private institutions has shown that test-optional admissions increase Pell Grant applicants, women, and first-time students from underrepresented racial/ethnic backgrounds (Bennett, 2021).

The examples above illustrate the complexities of fairness when we consider the vary unfair conditions of assessment globally. If we are to determine complexities related to fairness, including the ways assessment is interwoven with larger social issues such as public health crises, further understanding can also be gained by identifying key terms related to fairness. To this end, in the next section, we provide definitions useful in conceptualizing fairness.

Definitions: key terms related to fairness

Inherently, fundamental considerations of fairness are a part of education. When we narrow fairness applications to educational measurement alone, discussions of unfairness (fairness violations) arise across all settings, from elementary to secondary school group scoring programs to higher education admissions testing—as well as across purposes of testing, from classroom assessments to testing for licensure and certification. In this broad range of testing applications, it seems nearly impossible to begin a discussion of fairness without considering the larger context in which tests are used. This issue is ever more important when we use situated language frameworks in which local environments have a substantial influence on stakeholders impacted by tests and its scores: advisory board members, administrators, faculty, parents, professional organizations, students, tribes and tribal members, and the public (Gee, 2020; Mislevy, 2018). Within this context, we next describe key terms related to fairness. Our list of key terms includes both terms from the educational assessment community used traditionally in fairness related discussions and newer terms that reflect global calls for fairness and justice. These terms are organized in alphabetical order.

- *Anti-racist assessment.* These assessment practices disrupt racist beliefs around learning by actively confronting the economic, structural, and historical roots of inequality (Kendi, 2016). With anti-racist approaches to assessment, teachers and test designers “acknowledge both the current and historical role of race and racism in their own pedagogical and assessment practices” (Randall et al., 2021, p. 596).
- *Bias:* Sources of construct underrepresentation or construct-irrelevance variance may differentially disadvantage test-taker groups. In statistics, bias is identified through systematic error in a test score (American Educational Research Association et al., 2014).
- *Consequence:* Impact identifies the intended or unintended outcomes of using tests in particular ways, in certain contexts, with certain populations. Some consequences are directly related to the score interpretation and use, while others are related to testing contexts or unintended negative consequences (American Educational Research Association et al., 2014).
- *Culturally responsive assessment:* As explained by Montenegro and Jankowski (2017), culturally responsive assessment is “mindful of the student populations the institution serves, using language that is appropriate for all students when developing learning outcomes, acknowledging students’ differences in the planning phases of an assessment effort, developing and/or using assessment tools that are appropriate for different students, and being intentional in using assessment results to improve learning for all students” (p. 10) (See also Hood et al., 2015).
- *Culturally responsive indigenous evaluation:* Also known as an Indigenous Self-Determination Evaluation Model, CRIE “respects, recognizes, and values the inherent worth of Indian culture; is responsive to the communities’ needs as voiced by all members of

the tribal community; builds evaluation designs and processes around Indian assets and resources; and literally and figuratively employs Indians in every part of the process (program, policy, implementation, evaluation) to heal, strengthen, and preserve Indigenous societies for the next 7 generations" (Bowman, 2005, p. 8).

- *Culturally sustaining assessment*: As explained by Randall et al. (2021), "culturally sustaining approaches to assessment (a) draw on Black, Indigenous, People of Color (BIPOC) students' funds of knowledge (Vélez-Ibáñez and Greenberg, 1992), (b) are connected to the lives of these students, (c) allow them to demonstrate their competence in a variety of ways through community cultural wealth (Yosso, 2005), and (d) are embedded within a culturally sustaining curriculum. Such an approach would 'perpetuate and foster ... linguistic, literate, and cultural pluralism as part of the democratic project of schooling and as a needed response to demographic and social change' (Paris and Alim, 2014, p. 88)" (p. 596) (See also Ladson-Billings, 1995).
- *Disparate impact*: Differences in educational outcomes may result from facially neutral policies or practices. When used as both a statistical and conceptual tool, disparate impact analysis allows detailed analysis educational consequences, as well as legal strategies that may be used to redress inequity (Poe and Cogan, 2016).
- *Equity*: Gee (2008) calls for assurances that every individual has the opportunity to develop an identity as a competent learner, participate in communities of learning, and sustain a learning trajectory. Equity-centered design acknowledges that students have rich backgrounds of experience that, when acknowledged, provide opportunities for knowledge demonstration (Oliveri et al., 2020; Pullin, 2008).
- *Fairness*: "Validity of test score interpretations for intended use(s) for individuals from all relevant subgroups. A test that is fair minimizes the construct-irrelevant variance associated with individual characteristics and testing contexts that otherwise would compromise the validity of scores for some individuals" (American Educational Research Association et al., 2014, p. 219).
- *Opportunity to Learn (OTL)*: Exposure to particular knowledge, skills, and attitudes needed for curricular success. Consideration of OTL is important for the study of alignment between tests and curriculum, as well as allocation of resources needed to assure learning for all students (Moss et al., 2008).
- *Validity*: Extent to which evidence and theory support a specific interpretation and use argument. As is the case with fairness and reliability—the foundations of educational measurement—validity is considered as a process of evidence gathering (American Educational Research Association et al., 2014).
- *Reliability/Precision*: The degree to which test scores are consistent over repeated test applications. A test is said to provide evidence of reliability/precision when a measurement process is dependable, consistent, and free from random error (American Educational Research Association et al., 2014).
- *Social Justice*: Theories holding that fairness is understood through analysis of social contracts, distributive principles, and communal interaction. While theories of social justice vary, each maintains a commitment to principled strategies aimed at understanding and reducing inequality (Rawls, 1971/1999; Young, 2011).
- *Universal Design*: Approaches to educational measurement that maximize test accessibility for all test takers. Practices of universal design ensure that a test is fair for all test-takers, regardless of gender, age, language background, socioeconomic status, or disability (American Educational Research Association et al., 2014).

In general, some concepts—such as bias and reliability/precision—fall into technical work associated with educational measurement. Other concepts—such as culturally responsive assessment—are often associated with pedagogical practice. And yet other concepts, such as disparate impact, are associated with legal precedent. When studying fairness, it is important to emphasize commonalities among communities, from obligations to stakeholders to consideration of multidisciplinary collaboration. However, it is equally important to recognize that these definitions themselves are not without critics. For example, Randall et al. (2021) argue that OTL "has been used to justify construct definitions that exclude/attempt to erase the ways of knowing and understanding of BIPOC students. Simply put, constructs are defined in such a way that privilege whiteness and then BIPOC communities are informed that they simply have not had the opportunity to perfect/improve their whiteness" (p. 85). When defined with recognized qualifications, the terms defined above are one way of opening portals to common frames of reference (Meyer and Land, 2006).

Various fairness definitions have been offered in the *Standards for Educational and Psychological Testing* as well as educational measurement guidelines (American Educational Research Association et al., 2014; ETS, 2014; ITC, 2018). For a historical review of the *Standards*, see Sireci and Randall (2022). As Zwick (2019) has noted, increasing awareness of standards allow stakeholders to reach informed selection decisions, use multiple measures in making those decisions, and maintain decision transparency.

The best-known articulation of standards is that issued, in its present form, by three leading disciplinary organizations: American Educational Research Association [AERA], American Psychological Association [APA], and National Council on Measurement in Education [NCME]. With origins in 1952, the present version of the *Standards* established fairness as a center of evidence equal to validity and reliability as a foundational concept (American Educational Research Association et al., 2014; American Psychological Association and Committee on Test Standards, 1952). As noted in the definition provided above, fairness is understood as the validity of test score interpretations for intended uses applied to individuals from all relevant subgroups. Further, a test is said to be fair if it minimizes the construct-irrelevant variance associated with individual characteristics and testing contexts that otherwise would compromise the validity of scores for some individuals. In associating fairness with validity, the authors demonstrate the integrative value of fairness as a fundamental category of evidence. Beyond the definition, the *Standards* for fairness focus on minimizing barriers to valid score interpretations, providing detailed comment on accommodations and safeguards, and emphasizing the general conditions needed allow diverse student groups opportunities to demonstrate the construct under examination. As such,

the authors adopt a distributed perspective in which fairness is both the goal for all testing applications and the responsibility of all parties involved in testing.

Of equal interest are the *ITC Guidelines for the Large-Scale Assessment of Linguistically Diverse Populations* (International Test Commission, 2018) and the *ETS International Principles for Fairness Review of Assessments* (Educational Testing Service, 2016). Both are focused on testing within or across countries or regions that are linguistically and culturally diverse. For example, the *International Test Commission's (2018) Guidelines* "are designed to inform test developers, psychometricians, and test users of the considerations that should be made to help ensure test fairness and score comparability to support meaningful inferences in culturally and linguistically diverse contexts" (p. 3). Emphasizing diversity, the *ITC Guidelines* define fairness as evidence that an adapted assessment—changes made in content, format, or test administration to increase access for cultural or linguistic groups—will result in valid demonstration of test-takers construct knowledge. In its definition of fairness, ETS cites the *Standards* (2014). These guidelines and principles are important to understanding the factors that impact fair assessment in diverse populations of test-takers, including legal language status, language of instruction, and resources for adapting tests. Adopting the sociocognitive and sociocultural perspectives identified above are a great advantage in understating diversity.

Considerations: The future of fairness in measurement

While Zwick (2019) has noted the importance of using existing standards to deepen stakeholder perspectives, she has also advocated the importance of candid and clear communication. As she observes, frank and honest communication allows identification of common ground among stakeholders, including discussions of test fallibility and avoidance of defensiveness. She is cautious, however, in recommending a single solution model to the solving the challenges of fairness in educational measurement. In her discussion of bias, for example, she quotes Cronbach (1976, p. 31): "Make no mistake. The issues will not be settled by mathematical specialists." Standards can't stop student protests, make governments restore the internet, or erase decades of racist, classist, sexist gatekeeping.

To try to imagine a discussion of fairness today without considering these larger social implications is shortsighted, but there are real questions as to what future of fairness is to be in educational assessment. To those ends, we offer four considerations as a way to reimagine the Gipps and Stobart discussion of relationships among equity, access, curriculum, and assessment in the previous edition of this Encyclopedia (2010, Table 1, p. 58).

- *Consider fairness as a form of purpose pluralism.* Newton (2017) has called attention to the significance of purpose pluralism by noting that "assessment design should be driven by a multiplicity of assessment purposes simultaneously" (p. 5). In advancing purpose pluralism, he describes the tensions between purism (a fixed belief that an assessment should be used for a single purpose) and pluralism (a fluid belief acknowledging the many aims and perspectives involved in coordinating the activities of test designers and users). In proposing purpose pluralism, Newton identifies important perspectives related to information quality (targeting use of assessment results to make decisions, with emphasis on a trustworthy and transparent basis for making important decisions), expertise (emphasizing fidelity to a specific and prespecified cluster of learning outcomes, with attention to providing assessment justification), and engagement (focusing on the consequences arising from anticipating assessment impact for various participants, with variations regarding how positive consequences may be achieved). In applications of purpose pluralism to fairness, it may be useful to think about a central definition that can be applied to a specific assessment, with tailored versions of that definition shaped by various stakeholders. Evidence of fairness can then be gathered in accordance with these definitions, with claims made in cases where the definitions are congruent, and qualifications made in cases where the definitions are incongruent.
- *Consider fairness as an ongoing process.* While statisticians are likely correct in noting that answers related to bias may not be settled by mathematical specialists, it is equally true that much of our understanding of fairness has benefitted enormously by psychometric analysis in which statistical methods are used determine disparate impact. In seminal work, Cleary (1968) used general linear modeling techniques to target evidence of test bias based on whether or not the criterion score was consistently too high or too low for members of the subgroup. This work combined emphasis on both social goals of equity and statistical goals of production. Perhaps, in the future, it will be equally true that questions regarding fairness will be answered by more fully explicating interpretation and use of scores (Kane, 2013) as well as their social consequences. As Camilli (2006) has presently observed, test developers and teachers alike are embedded in social contexts. The future may therefore well be determined by reconciliation of that situatedness—in terms of transparent test construction and clear community communication on the part of test developers, careful test selection and anticipated consequences on the part of teachers, and sustained research and action on the social uptake of test results. Sustained research and action on the social uptake of test results would invite the linking of historical injustice to current action and ongoing work toward achieving justice for all test takers (Hood and Hobson, 2008).
- *Consider fairness as advanced through anticipatory design practices.* The 21st century has witnessed a variety of consequence-centered, anticipatory approaches to designing a variety of assessment genres. These approaches find their origin in work by Mislevy et al. (2003) in Western theory. Using a conceptual assessment framework, evidence-centered design uses model-based reasoning to identify conceptual, delivery, scoring, and reporting models for any given measurement episode. This assessment framework has been followed by related design approaches, including Integrated Design and Appraisal Framework (IDAF, Slomp, 2016),

expanded evidence-centered design (Arieli-Attali et al., 2019), and equity-centered design (Oliveri et al., 2020). Similarly, theory of action techniques have been used to conceptualize the educational effectiveness of an innovation in terms of governing variables (curricular models), action strategies (curricular delivery strategies) and impact (consequences of those strategies) (Argyris, 1997). When applied to educational tests, classroom assessment, and community education evaluation, this approach holds the potential to help identify patterns of interactions among stakeholders and various forms of consequences, both intermediate and long term (Hazelton et al., 2021). In addition, a decolonial approach to anticipatory design is culturally responsive indigenous evaluation in which evaluators do not “impose a model, evaluation design, instruments, or tools upon the members of that community” (Waapalaneexkweew, 2018, p. 546). Instead, through “recognition of the legal implications of Indigenous sovereignty,” designers move beyond the “beads and feathers’ linguistic and cultural aspects of evaluation to work with tribal governments and communities as sovereign partners,” in the design, adaptation, problem-solving, and reporting of evidence-based evaluations (Waapalaneexkweew, 2018, p. 550). Taken together, evidence-centered design approaches, theory of action techniques, and culturally responsive indigenous evaluation provide powerful ways for assessment specialists and classroom teachers to consider factors related to evidence of fairness, validity, and reliability in a given measurement episode.

- *Consider fairness as understood through multidisciplinary and community collaboration.* While the twentieth century may be said to have proposed solutions to social challenges, the 21st century may be said to have viewed those very solutions as problems. From the present vantage point, addressing these problems will require multidisciplinary collaboration. As Oliveri et al. (2021) have shown in the case of a complex digital assessment, coordination of multidisciplinary action involving a wide variety of community stakeholders and experts (from computer science to policy analysis) is needed to maximize the desired, intended consequences from the use of an assessments—and to minimize undesirable, unintended effects.

Conclusion

Whether framed in terms of broad societal issues such as resource distribution or specific applications such as admissions testing, fairness is a critical subject to discuss in educational assessment. While the concepts involving evidence of fairness may be complex, they are nevertheless accessible. Even the most complex legal, statistical, and community-based discussions of fairness are possible, especially when these discussions are framed—at the outset—as accessible through multidisciplinary collaboration. Often, fairness is envisioned as an unattainable goal, but present international circumstances described in the introduction to this Encyclopedia entry reveal that position to be untenable. While it may be argued that it was impossible to prevent the adverse consequences identified in the case studies drawn from Chile, the Middle East and North Africa, and the United States, it can be equally argued that intentional use of the perspectives provided here could have lessened their impact. And in the wake of the COVID 19 pandemic and Black Lives Matter movement, discussions of fairness can never again be extracted from the social fabric in which fairness is woven.

History

The term Classical Test Theory (CTT) started appearing with the publication of Lord and Novick's book *Statistical Theories of Mental Test Scores* (1968), primarily to differentiate Item Response Theory (IRT) and the assessment topics that preceded it (see "Item Response Theory (Unidimensional)" by Terry Ackerman this volume). Since CTT encompasses a wide range of psychometric measurement issues, which continued to expand into the formulation of contemporary test models, the term is somewhat misleading in that CTT does not imply a singular test measurement theory divergent from modern assessment development practices.

The historic context that led to the development of what is presently referred to as CTT, has long cultural antecedence in assessment practices going back to the early 7th century CE. The imperial Chinese civil service examination (Keju) system, believed to be in continuous operation from approximately 606 CE to 1905, is possibly the oldest systematic testing program in the world (Suen and Yu, 2006). What differentiates the Keju system from its contemporaries and earlier assessments, and thus warrants its inclusion in a discussion about CTT, is its appreciable focus on scoring consistency and the reduction of measurement error. Because of its use of oral examinations and constructed responses, the Keju system imposed specific question and response formats with the aim to assure consistency of performance evaluations. Albeit not statistically defined in psychology until the late 19th century, the desire for consistency in evaluating skills and knowledge would give rise to the initial interpretational context of classical test theory: reliability.

In a simplified overview, the development of classical test theory can be viewed through the lens of three measurement aspects: (1) Reliability, (2) validity, and (3) generalizability (McDonald, 1999). While these attributes are not independent of one another in contemporary general educational measurement/psychometric practice, their sequential historic formalization provides an evident progression of the CTT interpretational context in which observable test scores were defined.

True score

The scientific revolution of the 17th century provided the conceptual antecedents to many areas of modern science, including psychometrics. Scientific measurements and the concern with their precision morphed into what Traub (1997) discussed as the "zeitgeist at the turn of the 20th century, [which] was the notion of errors in scientific observations" (p. 8). The historic developments leading up to that point in time introduced the notion that an observable score, which we shall refer to as X , was not necessarily the true value of the quantified construct. Instead, the observable score was an adjusted true state or value of the measurement, which we shall refer to as the true score, or τ , affected by an exogenous source(s) of error, which we shall refer to as ϵ . In its simplest form, as reaffirmed by Gulliksen (1950) in his seminal book on CTT, *Theory of Mental Tests*, the relationship between the three terms can be expressed as:

$$X_{ij} = \tau_i + \varepsilon_i \quad (1)$$

where X is an observable score for person i on a test or item j , τ is the person's true score on that test or item, and ε is the measurement error for person i .

Eq. (1) represents the very core of classical test theory and is the equation most associated with it. It provides the general relationship between a person's observable quantified performance and the underlying true score of the criterion of interest. Deceptively simple, nearly the next 100 years were spent in providing the statistical links and relational definitions among these three terms in the framework of cognitive and non-cognitive assessments.

The ongoing statistical developments of the early 20th century and their adoption in psychology would express observed scores as realizations of a random variables, where a random variable was defined as a variable that takes on values according to a probabilistic function. The relationship between the observed score and the unobservable true score would be formalized as:

$$X|\tau_X \sim N(\tau_X, \sigma_\varepsilon^2) \quad (2)$$

where the observed scores in a population, given the same true score, are normally distributed with a mean equal to that true score and a variance equal to the variance across all observed scores in the population with the same true score. By extension the observed score and the true score have a bivariate Normal relationship as the true score itself is believed to vary across the population.

$$\tau \sim N(\mu_\tau, \sigma_\tau^2) \quad (3)$$

Here the true score, τ , is normally distributed with its specific population mean, μ_τ , and variance, σ_τ^2 .

It should be noted that the average of measurement errors, such as that depicted for a single measurement in Eq. (1), is believed to be equal to 0,

$$\mu_\varepsilon = 0 \quad (4)$$

as the errors in the measurements are believed to be random and independent of the true scores. Because the errors are independent of the true scores, errors should not covary systematically with the true score, meaning that their covariance (and thus correlation) should also be 0:

$$\sigma_{\tau,\varepsilon} = \rho_{\tau,\varepsilon} = 0 \quad (5)$$

It follows from the assumption of statistical independence between the true scores and the errors, and the assumption in Eq. (4) as it relates to Eq. (1), that the expectations (or means) of the three terms should relate to one another just as the terms in Eq. (1):

$$\mu_X = \mu_\tau + \mu_\varepsilon \quad (6)$$

However, given that the average error is believed to be zero, Eq. (6) can be simplified to:

$$\mu_X = \mu_\tau \quad (7)$$

where the average observed score is believed to be equal to the average true score. This notion further expanded from multiple measurements in the population to parallel assessments of the same examinee postulating that an examinee's average observed score across parallel assessments should equal their average true score. By the same convention it can be derived that the variance of the observed scores is equal to the sum of the true score and error variances:

$$\sigma_X^2 = \sigma_\tau^2 + \sigma_\varepsilon^2 \quad (8)$$

It follows that in Eq. (1) the observable quantity of the score X is associated with its known descriptive statistics and distributional characteristics, while the terms on the right side of the equation require modeling. While the relational aspects laid out in Eqs. (2)–(8) form the principal assumptions of CTT, much attention has been given to the estimation of the true score and error variances, as these are not directly observable. Due to the nature of Eq. (1), and the established relationships between terms, if one of the two, true score or error quantities, could be approximated, Eq. (1) would become a simple equation with one unknown for which we can solve. Arriving at a universally accepted approximation, or practical analog, of either the true score or error, has proven to be challenging as measurement instrument attributes (viz. test characteristics) have made finding efficacious solutions elusive. Alternatively, approximating distributional estimates of these quantities has enabled further inferences about multiple measurements from either the same student or for a sample of examinees from the population.

Models

The CTT model in Eq. (1) is typically introduced, as we have done, in the context of an observable measurement akin to a performance evaluation. In educational measurement we could think of this performance evaluation, the observed score X , as the score a student may get on either a single test item or an overall assessment instrument. Because of this, the terms "item" and "test" will largely be used interchangeably. In fact, the assumptions of the CTT framework remain the same, regardless of the granularity at which they are applied, providing that the tenets of the theory that the observable score is comprised of a true score and error are applicable. Subsequently, CTT extends into the treatment of multiple observed scores measuring a common construct. The

approaches by which the relationship of multiple observed scores and related true scores can vary are commonly referred to as the classical theory true score measurement models.

Parallel

The parallel, or classically parallel, CTT true score model reflects the original sentiments of CTT in that each observable item score, or test score, measuring the same construct, is parallel to one another in the sense that for person i , their observed score j ($X_{i,j}$), is comprised of a person specific true score, τ_i , and person random error realization, ε_i ; basically the CTT model in Eq. (1). What becomes more explicit in the parallel measurement model is that this relationship is expected to hold across all parallel construct measurements for observed scores $j, j+1$, etc. Table 1 provides the general assumptions of this assumption for the expected observed score, the definition of the person specific true score, and the standard deviations of true scores and errors across multiple measurements.

If the variability of true scores and errors across measurements is constant then the average observed scores should also be equivalent (model 1 assumptions a, c and d in Table 1). This restrictive assumption of the parallel model, while computationally desirable as any construct relevant measurement would depend on only two parameters, is practically unrealistic.

Tau-equivalent

The assumptions of the parallel model (1.a and 1.d in Table 1) suggest that any measurement instance of the construct is affected by the random error, which is independent of the item. Whether considering a repeat measure on a single item (j), or a measurement of the same construct on a subsequent item ($j+1$), assuming that there are no changes in error variability across these instances is unlikely given that a variety of exogenous factors typically affect measurement.

The tau-equivalent measurement model relaxes the assumption of equivalent errors with the resulting assumption that the hypothetical measurement error across instances (items, test, etc.) will be different (Eq. 9 and assumption 2.d in Table 1).

$$\sigma_{\varepsilon j} \neq \sigma_{\varepsilon j+1} \quad (9)$$

Given the nature of observed test/item scores, the tau-equivalent model (and all subsequent models) is more closely aligned to practical observations of psychological measurements than the classically parallel true score model. Since the underlying true score that generates an observed score on item j and subsequent measurement instances ($j+1$) is believed to be the same, we refer to the models as tau-equivalent.

Essentially tau-equivalent

All CTT measurement models postulate that a universal person specific true score is the generative source of the observed score. However, given that the true score is believed to follow a distribution in the population, Eq. (3), a person's true score on a specific item or test (j), $\tau_{i,j}$, can be thought of as a realization of the person's specific true score, τ_i . When discussing distributional

Table 1 Classical test theory measurement models relating observable test scores with unobservable true scores.

	Model	Observed score	Assumptions
(1)	Parallel	$X_{i,j} = \tau_i + \varepsilon_i$	(a) $\mu_{Xj} = \mu_{Xj+1}$ (b) $\tau_i = \tau_{i,j} = \tau_{i,j+1}$ (c) $\sigma_{\tau j} = \sigma_{\tau j+1}$ (d) $\sigma_{\varepsilon j} = \sigma_{\varepsilon j+1}$
(2)	Tau-equivalent	$X_{i,j} = \tau_i + \varepsilon_{i,j}$	(a) $\mu_{Xj} = \mu_{Xj+1}$ (b) $\tau_i = \tau_{i,j} = \tau_{i,j+1}$ (c) $\sigma_{\tau j} = \sigma_{\tau j+1}$ (d) $\sigma_{\varepsilon j} \neq \sigma_{\varepsilon j+1}$
(3)	Essentially tau-equivalent	$X_{i,j} = (\tau_i + \mu_j) + \varepsilon_{i,j}$	(a) $\mu_{Xj} \neq \mu_{Xj+1}$ (b) $\tau_i = \tau_{i,j} - \mu_j = \tau_{i,j+1} - \mu_{j+1}$ (c) $\sigma_{\tau j} = \sigma_{\tau j+1}$ (d) $\sigma_{\varepsilon j} \neq \sigma_{\varepsilon j+1}$
(4)	Congeneric	$X_{i,j} = (\lambda_j \tau_i + \mu_j) + \varepsilon_{i,j}$	(a) $\mu_{Xj} \neq \mu_{Xj+1}$ (b) $\tau_i = (\tau_{i,j} - \mu_j) / \lambda_j = (\tau_{i,j+1} - \mu_{j+1}) / \lambda_{j+1}$ (c) $\sigma_{\tau j} \neq \sigma_{\tau j+1}$ (d) $\sigma_{\varepsilon j} \neq \sigma_{\varepsilon j+1}$

Note. In the table above X represents the observable score, τ the unobservable true score and ε the measurement error for person i on item j .

characteristics, such as mean and variance, we tend to think of these parameters in the context of a latent trait distribution as location (or precision) and scale respectively (Graham, 2006). Subsequently, the essentially tau-equivalent measurement model holds that while essentially all measurement instances for a person share the specific true score, they vary in the items' precision to measure the true score. Table 1 shows the corresponding CTT model (3), and how the essentially tau-equivalent model varies from the tau-equivalent predecessor by an additional parameter μ_i .

The assumption of a person item true score (Eq. 10 and assumption 3.b in Table 1) is that a person's specific true score, τ_i , is shifted by an item location or precision parameter, μ_i .

$$\tau_i = \tau_{i,j} - \mu_j = \tau_{i,j+1} - \mu_{j+1} \quad (10)$$

It thus follows that if items' precision parameters (for any item j , $j+1$, etc.) could be subtracted from the corresponding person specific true scores on those items ($\tau_{i,j}$, $\tau_{i,j+1}$, etc.), we should recover the person specific (overall) true score.

Congeneric

Comparing the CTT measurement models side-by-side in Table 1, we can deduce that as assumptions about an examinee's true score and measurement error become less restrictive, additional parameters are needed to accurately capture the relationship (Jöreskog, 1971). Thus, the congeneric model expands further on the essentially tau-equivalent model in that in addition to its precision parameter the congeneric measurement model introduces an item true score specific scale parameter, λ_i .

$$X_{i,j} = (\lambda_j \tau_i + \mu_j) + \varepsilon_{i,j} \quad (11)$$

The scale parameter of the congeneric model provides a mechanism by which the dispersion of the centered item true score ($\tau_{i,j} - \mu_j$), which we encountered in the essentially tau-equivalent model, can be adjusted so as to reproduce the person's true score scale. In essence assumption 4.b in Table 1 shows that an item's true score requires correction in terms of both precision and scale in order to ascertain the person's true score on the measured construct.

With the specification of the congeneric model, CTT acquired a more flexible form, and one that would lend itself naturally to modern psychometric practices. For example, Raykov (1997) demonstrated how Structural Equation Modeling (SEM) could be used to fit the congeneric measurement model to observed data (and therefore all other discussed CTT models by imposing constraints) to determine both the fit of the model, given the data, as well as to derive latent trait variance estimates for purposes of computing CTT derived reliability estimates (see Interpretational Contexts below).

CTT as a special case

Based on the focus of the afore discussed models, CTT's principal concern is one of attempting to understand the nature of the true score and how concrete assumptions about its realization and its relationship to error relate to observable data. Given the continued development of models that attempted to ascertain the representative link between observable data and the true score, it should come as no surprise that a general form, one to encompass a multitude of varying levels of measurement and distributional attributes, was derived. Much as it is the case with the generalized linear model, a generalization of the link between the latent trait true score and observable scores lead to the development of the generalized latent variable model by Skrondal and Rabe-Hesketh (2004). While their work provides conceptual extensions to the classical test theory framework, the relationship between the components of the generalized latent trait model to CTT may not be immediately clear. Arguing for the similarities between IRT and CTT, Lewis (2007) extends backwards from the generalized latent trait model and provides a discussion of how components of CTT are represented in the generalized form. In his treatment, CTT is viewed as a constrained special case of the generalized latent trait model, "with the qualification that a suitable substitute for $[\tau]$ must be found to approximate the biserial correlation", $\rho_{\tau,j}$ between the random latent true score and the item score (p. 42) in order to establish the link.

Interpretational contexts

In isolation, Eq. (1) and the true score models provide a rather disenfranchized view of CTT and their interpretation within the educational measurement domain. As noted earlier, historically CTT has been contextualized by a series of frameworks within which aspects of the theory were used to provide solutions to measurement concerns. These interpretational contexts have ranged from the very fundamental, such as reliability, to the very applied, such as maintaining assessment score interpretation across multiple test forms. Most of these contexts have merited the writing of separate books, and countless articles, dedicated to the intricacies of those respective domains. It is therefore far beyond the scope of this brief introduction to CTT to enumerate or elaborate on these applications adequately. Nevertheless, it would be remiss not to acknowledge the progressive historic applications in which CTT has been, and continues to be, a prominent keystone.

Reliability

Growing out of the works by [Pearson \(1901\)](#), [Spearman \(1904\)](#) and [Thorndike \(1907\)](#), a new direction formed in the social sciences of the early 20th century in which the variance of one variable, attribute or characteristic was systematically explained by the variance of another in what is today familiar to most as the Pearson product-moment correlation. The resulting application of correlation to multiple performance scores, believed to assess the same or common parts of a single construct, provided further statistical connectivity between observed measurement scores, as realizations from distributions, and the hypothetical person latent (unobservable) construct true score.

Today, measures of consistency are inseparable from the development and evaluation of assessment instruments. However, as psychological measurement was developing and the edicts of CTT were gaining traction among the practitioners and thought-leaders of the times, the context growing around CTT became one of reliability. This drive for CTT's application in this context is evident from [Kelley's \(1921\)](#) verbalization of "the need of a standardized procedure in measuring the reliability of the tests which are in use, and with the hope that it will encourage such study and discussion as will lead to a unified practice" (p. 377).

As [Kelley \(1916\)](#) himself would show, and [Thurstone \(1927\)](#), [Gulliksen \(1950\)](#), and [Lord and Novick \(1968\)](#) would reintroduce, the reliability of the observed scores (ρ_X) could be expressed as the squared correlation between the observed scores and latent true scores ($\rho_{X,\tau}$), a concept fundamental to CTT. This squared correlation could be expressed as the ratio of the respective variances, or the proportion of systematic variance:

$$\rho_X = \rho_{X,\tau}^2 = \sigma_\tau^2 \sigma_X^{-2} = 1 - (\sigma_\epsilon^2 \sigma_X^{-2}) \quad (12)$$

where if the true score variance, σ_τ^2 , numerator is larger than the variance of the observed score, σ_X^2 , the expected theoretical reliability will always be positive, suggesting a higher degree of consistency as the quotient nears to 1.0.

As was conveyed through the previous sections, ascertaining the standard deviation of the unobservable true score would require additional assumptions. It is herein that the initial CTT formulation intersects with the first true score model, the classically parallel measurement model, in that in the absence of knowledge of the true scores, variance of the true score can be derived as

$$\sigma_\tau^2 = \sigma_X^2 \rho_{XW} \quad (13)$$

where the estimate ρ_{XW} in [Eq. \(13\)](#), is the correlation between observed and classically parallel scores (or observed scores X and W) and is assumed to be equivalent to the reliability in [Eq. \(12\)](#) ([Lord and Novick, 1968](#), pp. 60–61).

Substituting [Eq. \(13\)](#) into [Eq. \(12\)](#), [Gulliksen \(1950\)](#) showed that the estimate of reliability becomes just the square of the correlation between observed and a classically parallel score, and is equivalent to the proportion of variance in the observed score accounted for by the variance in the classically parallel score (p. 23). For further reading see "[Reliability](#)" by Klaas Sijtsma and Julius Pfadt this volume.

Validity

CTT has been critiqued and exalted, deemed in- and out of fashion, and experienced more than one revival in which its models have been reevaluated and cast in a new perspective. Regardless of the context in which CTT is used to address psychological measurement features, at the heart of the theory resides the belief in a person specific true score, τ_i , that gives rise to the observed score. Consequently, if that belief is incorrect, or is inappropriately specified, then CTT's utility is brought into question (see "[Validity](#)" by Suzanne Lane this volume).

In the 1950s and 1960s, an ongoing deliberation about what an unobservable true score actually represents, CTT experienced a conceptual impasse. [Rust and Golombok \(2009\)](#) provided an overview of some of the principal criticisms of the theory of true scores, and discussed how subsequent conceptualizations enabled the support for CTT (pp. 35–42). Notably, the treatment of the true score as a strong statistical theoretical construct ([Novick, 1966](#)) by which computational solutions are derived seemed to prevail until interpretational requirements moved the debate to arguments for defining the true score in terms of trait or function. [Angoff \(1988\)](#) further elaborates on the practical aspects in which the true score is described via a collection of evidence to substantiate the construct with which it is associated where the "responsibility for validation falls to [...] the person willing to claim that certain inferences may be validly drawn from the test scores" (p. 29).

Many of the discussions regarding the true score definition and its relationship to CTT concentrated on substantive meaning and practical applications ([Messick, 1994](#)). However, the statistical methods associated with the diverse discussions of validity, had been surprisingly limited, frequently simplifying to a correlation between the observed score and a criterion score. [Zimmerman \(1998\)](#), in a reversal of this process, focuses on the problematic CTT assumption of uncorrelated errors and parallelism, and explains validity in the context of scores on a criterion and predictive validity of a test with respect to itself. "It should be emphasized, however, that the modified definition does not overcome all difficulties arising from correlated errors. Rather, the complications are transferred to the task of estimating validity by practical methods" (p. 248).

Generalizability

With two out of the three terms in [Eq. \(1\)](#) being unobservable, it is perhaps to be expected that as assumptions and constraints were imposed on the true score and error that questions regarding their nature became focal points of CTT. Just as was the case with

validity, in which a growing concern around the definition of the unobservable true scores became a central context for understanding CTT, so the nature of the errors became an imminent topic of concern.

While the treatment of the person specific true score in the presented measurement models in Table 1 evolves, the only discernible change regarding the error occurs between the parallel model and all others in that the random error is either equally variant across items or varies. Cronbach et al. (1963) recognized that this was problematic as it assumes a single homogenous source of error (regardless of the model), which is not only improbable but also impractical given the desire to disentangle the nature of the error affecting the true score. The concern about the inability to model the measurement error, particularly as it related to the estimations of reliability, evolved into generalizability theory (or G-theory), which “liberalizes classical theory by employing ANOVA methods that allow an investigator to untangle multiple sources of error that contribute to the undifferentiated [e] in classical theory” (Brennan, 2001, p. 3). Ultimately, G-theory provides a flexibility in evaluating measurement consistency and provides an estimated proportion in the total variance attributable to examinee facets, something not possible in CTT (see “Generalizability Theory and Applications” by Stella Kim, this volume, for an extended discussion of the framework).

Test development

All three of the previously identified CTT interpretational frameworks make important implicit connections to assessment design and development. However, one of the most effective applications of CTT has been in the realm of test development, which deserves a more direct treatment and elaboration.

From the previous delineation of the CTT models it follows that the parallel nature of tests is an important feature in CTT. Typical operationalized parallel test form development follows strict content blueprint guidelines, scoring and score reporting objectives, consistent testing experience directives and psychometric measurement model and test form statistical targets. In order to target parallel test development an additional set of assumptions in the form of domain sampling theory needs to be made. Domain sampling, in which all item samples considered for a specific blueprint attribute or student expectation are believed to be randomly equivalent, and thus item sets created from such item samples are assumed to be randomly parallel. Consequently, CTT test development implemented operational procedures aimed at preserving a CTT true score model, utilize information about item candidates (available items to be included in a test form) to deduce future item set (and total test form) statistics in order to approximate form parallelism.

The two fundamental classical item statistics used to describe the functioning of an item are item difficulty and item effectiveness. Item difficulty (p_j), for a dichotomously scored item (j), is given as the proportion of examinees who answered the item correctly out of all examinees.

$$p_j = \sum x_{ij} N^{-1} \quad (14)$$

where x_{ij} denotes the dichotomously (0—incorrect, 1—correct) scored responses for person i on item j , and N , total number examinees who received credit on the item (viz. provided a correct response for which they received 1 point).

Item effectiveness, also referred to as item discrimination, is given by the point-biserial correlation coefficient:

$$r_{xj} = ((\mu_+ - \mu_x) s_x^{-1}) \sqrt{(p_j (1 - p_j)^{-1})} \quad (15)$$

where μ_+ is the test score mean for those examinees who answered the item correctly, μ_x is the overall test score mean, s_x is the test score standard deviation, and p_j is the item difficulty in Eq. (14) (Crocker and Aligna, 2006, p. 317). Armed with the two estimates from Eqs. (14) and (15) several important CTT parallel form targets can be determined.

Consider the hypothetical item statistics in Table 2 for 10 items. Of the provided estimates, only item difficulty (first row) and item point-biserial correlation with the total score (fourth row) are computed based on the performance of an examinee population representative sample. All other estimates are derived.

Using the properties of the binomial distribution, the proportion correct can be transformed into the corresponding item variance as follows:

Table 2 Sample classical test theory item (j) analysis statistics.

Estimate		$j1$	$j2$	$j3$	$j4$	$j5$	$j6$	$j7$	$j8$	$j9$	$j10$	Sum
Proportion correct	p_j	0.73	0.70	0.63	0.56	0.54	0.50	0.43	0.36	0.32	0.30	5.07
Item variance	s_j^2	0.20	0.21	0.23	0.25	0.25	0.25	0.25	0.23	0.22	0.21	2.29
Item standard deviation	s_j	0.44	0.46	0.48	0.50	0.50	0.50	0.50	0.48	0.47	0.46	4.78
Point-biserial correlation	r_{xj}	0.25	0.26	0.30	0.39	0.44	0.43	0.38	0.37	0.35	0.31	3.48
Item “reliability index”	$s_j r_{xj}$	0.11	0.12	0.14	0.19	0.22	0.22	0.19	0.18	0.16	0.14	1.67

$$s_j^2 = p_j(1 - p_j) \quad (16)$$

where the item standard deviation (third row in [Table 2](#)) is simply the square root of the estimate in [Eq. \(16\)](#) above. It follows that the item “reliability index” ([Gulliksen, 1950](#), p. 377, [Eq. 22](#)), is the product of the item standard deviation and its corresponding point-biserial correlation.

Using these estimates the expected mean test score for a test form consisting of *any subset* of items can be taken as,

$$\mu_x = \sum p_j \quad (17)$$

with a corresponding test score standard deviation equal to the sum of all item reliability indices (products of item standard deviations and their point-biserial correlations):

$$s_x = \sum s_j r_{xj} \quad (18)$$

Thus, the 10-item set in [Table 2](#) yields an expected test score mean of 5.07,

$$\mu_x = p_1 + p_2 + \dots + p_9 + p_{10} = 0.73 + 0.70 + \dots + 0.32 + 0.30 = 5.07 \quad (19)$$

and a test score standard deviation of 1.67,

$$s_x = s_1 r_{x1} + s_2 r_{x2} + \dots + s_9 r_{x9} + s_{10} r_{x10} = 0.11 + 0.12 + \dots + 0.16 + 0.14 = 1.67 \quad (20)$$

The item estimates, or item parameters, can be further employed to determine test reliability (test item internal consistency) as demonstrated by [Kuder and Richardson \(1937; KR-20\)](#):

$$\rho_X = \left(K(K-1)^{-1} \left(1 - \sum s_j^2 s_{x-1}^2 \right) \right) \quad (21)$$

where K is the number of items on the test, $\sum s_j^2$ is the sum of all item variances and s_x^2 is the total test score variance. All of these estimates can be derived from the two CTT item analysis statistics provided in [Table 2](#) discussed earlier. In the provided example in [Table 2](#) the resulting test reliability can be computed as:

$$\rho_X = (10 \times (10-1)^{-1}) \left(1 - (2.29 \times (1.67^2)^{-1}) \right) = 1.11 \times (1 - 0.82) = 0.20 \quad (22)$$

While not a strong indication of measurement consistency, the low test reliability is to be expected given the small number of items on the test (see [Gulliksen, 1950](#), pp. 74–86). Following [Eq. \(12\)](#) we can further express the square root of the test reliability to denote the approximation of the correlation between the test score and the unobservable true score,

$$\rho_{X_t} = \sqrt{\rho_X} = \sqrt{0.20} = 0.45. \quad (23)$$

In the provided example, drawing subsequent 10-item sample sets, which meet blueprint and test assembly requirements, can be evaluated in the context of their psychometric properties. Computing the aforementioned estimates enables the practitioner to evaluate competing sets’ statistical parallelism. Using the CTT framework, we demonstrated how selecting items based on their CTT item parameters can target parallel test form score means, standard deviations and test reliability properties. These relationships between CTT item analysis statistics (from such sources as pilot studies, field testing, etc.) and test development objectives have found applications in a variety of uses, far beyond their original conceptualizations. For example, using the above demonstrated relationships, psychometricians have imbedded these estimate relationships as test development targets in automated test assembly ([Parshall et al., 2002](#), pp. 113–123), and computer-based testing ([Gibson and Weiner, 1998](#)) to name a few.

Discussion

As is the case with many scientific fields, foundational concepts echo through the ages of innovation and development, often lending themselves to new solutions via original precepts. Arguably, CTT has provided a lasting framework through which psychometrics has grown into an indispensable expertise for many industries and utilizations in assessment development, educational measurement and cognitive- and non-cognitive evaluations. While perhaps most prominently immortalized in its application to reliability estimation and test development, CTT remains relevant as the original principle of the psychological measurement framework.

With the cyclical resurgence of the CTT specific reliability, validity and generalizability contexts, CTT has undergone several modernizations. Analogous to the validity and fairness discussions of the 1950s to 1990s, as issues of inclusivity and antiracism are proactively voiced, CTT will require a transparent and honest substantiation within a just assessment approach ([Randall, 2021](#)). However, whether moving the test theory discussion from parallel test form reliability to SEM estimation of true score and error variances, or expanding the congeneric true score model to a generalized latent trait design, CTT, despite its name, continues to motivate the evolution of test theory.

Introduction to generalizability theory

Measuring student achievement is an essential part of education, allowing for tracking of student progress and evaluation of teachers, schools, or educational systems. Thus, it is critical to educators to ensure quality measurement. The notion that measurement is subject to various sources of error spawned the development of psychometric theories that each takes a unique approach to quantifying measurement error in observed data. In the context of educational measurement, the word *error* does not mean a mistake that is correctable or avoidable, but it is rather an innate property of measurement. Unlike the natural sciences, most educational and psychological research centers around a trait or construct that is not directly observable. Thus, a measurement procedure designed to capture the amount of that trait a person possesses, inevitably results in fluctuating observed scores. The term “reliability” is often used to quantify the extent to which a measurement procedure yields consistent results, (i.e., observed scores) over replications of the measurement procedure.

There are two broad perspectives on true score: expected-value and latent-trait perspectives. Our focus here is on the former. From the expected-value perspectives, *true score* for a person is defined as an expected value of the person’s observed scores obtained from a hypothetically infinite number of replications of a measurement procedure, each being implemented under similar conditions. In this context, one’s observed score presumably fluctuates from one instance of the measurement procedure to the next. This fluctuation is a result of error. An error score is defined as a deviation of an observed score from a true score. In practice, the variance of error scores is quantified and used to determine the extent to which measurement results are consistent across hypothetical replications of a measurement procedure. The larger the variance of error scores (meaning one’s observed scores vary greatly from one administration to another), the less reliable measurement results are.

Of course, it is almost impossible in reality to repeat the measurement procedure over and over on a sample of examinees from a population and thus, the conceptualization of true scores, observed scores, and error requires a conceptual and hypothetical proposition. Among well-established psychometric theories, generalizability theory has been recognized as a powerful and comprehensive framework for identifying and quantifying multiple sources of error in observed scores over investigator-identified conditions of measurement. Generalizability theory breaks measurement errors into the contribution of multiple sources by decomposing the variance of the overall error into variance component associated with each source of error. In doing so, the analysis of variance (ANOVA) procedure typically is used. Often, classical test theory (CTT; Lord and Novick, 1968) is conceived as the predecessor to generalizability theory with the analytical support of ANOVA. However, Brennan (2001a) pointed out that generalizability theory is not a just simple association of the two parental components, and its power mainly comes from its conceptual framework.

Roughly speaking, generalizability theory consists of two distinct conceptual and analytical phases: (1) G (generalizability) studies and the universe of admissible observations (UAO) and (2) D (decision) studies and the universe of generalization (UG). This chapter provides some fundamental concepts of generalizability theory and its application to a set of example data. Note that the terminologies and notation used in this chapter are similar to Brennan (2001a). Equations presented in this chapter

are mostly expressed in terms of parameters, and can be easily replaced by estimators which are denoted with a hat ($\hat{\cdot}$). For a more thorough treatment of generalizability theory, readers might refer to Brennan (2001a).

Universe of admissible observations and G studies

The first phase starts with defining the UAO for a given measurement. The UAO is determined by a set of conditions of measurement called “facets”, as well as the way that these facets are associated with one another (crossed vs. nested). A facet refers to a set of conditions of measurement that constitutes a measurement procedure. Some examples of facets that may characterize a typical achievement test include items, occasions, testing modes, raters, item formats, and content domains. For example, consider a situation where a test is being newly developed to measure spelling knowledge for young children. The test developer might identify some characteristics of items that are considered appropriate for the intended purpose. Any item that possesses such presumed characteristics constitutes an admissible condition of measurement for the item facet. Then, any specific items used in a particular measurement procedure can be viewed as a sample randomly selected from the very large, or possibly infinite, universe of such items. The terms “facet” and “universe” are used for conditions of measurement (i.e., sources of error), while the terms “object of measurement” and “population” are reserved for those being assessed (i.e., persons in most educational settings).

Now suppose the investigator assumes that any person (p) in the population can take any item (i) in the universe. This is a verbal description of a “crossed” UAO structure, which is denoted $p \times i$. Once the UAO is defined, a study is conducted to collect data for estimating variance components. Such a study is called a G study. The design of a G study is identified by the investigator such that the variance components of all important facets can be estimated. When the UAO has a crossed structure, there are two possible data collection designs the investigator can use for a G study: the $p \times i$ or $i : p$ design. The $p \times i$ design involves each person taking the same set of n_i items. For the $i : p$ design, by contrast, each person responds to a different set of n_i items. The primary purpose of a G study is to estimate variance components (VCs) based on the data collected using either the crossed or nested design. As seen in this example, the G study design may or may not be the same as the structure of the UAO.

The UAO can have as many facets as the investigator believes are important to the particular measurement procedure. For example, the investigator might consider testing occasions (o) as another substantive source of measurement error, in addition to items. Then, the UAO structure will likely be $p \times i \times o$, and the G study data can be collected using the fully crossed design, $p \times i \times o$, or one of the nested designs such as $p \times (i : o)$ or $(i \times o) : p$. Generalizability theory indeed is most useful when multiple sources of error are identified and hence disentangled. Defining the UAO also depends on the size of the universe of each facet. When the population for the object of measurement and the universe of every facet are infinite, at least in theory, the model is called a random effects model. Strictly speaking, this assumption of an infinite universe is less likely to be perfectly true, but often a necessary conceptualization for most studies. When some facets have a finite universe while other facets are infinite in size, it is a mixed model. For example, suppose that each item in the universe is associated with one of a few content categories and the content-category facet (k) has a finite number of conditions in the universe. In this case, the UAO structure will be $p \times (i : k)$ and it is likely that a G study involves using all conditions in the universe for k .

G study variance components (VCs)

In generalizability theory, observed scores are represented with respect to effects of several components. Often, defining the components involved in a certain G study design can be supported by use of a Venn diagram. Venn diagrams for the two designs ($p \times i$ and $i : p$) described earlier can be found in Fig. 1. Each circle in the Venn diagram is associated with a facet, and the total number of components in any design is equal to the number of distinct areas in the Venn diagram. A distinction between the crossed and nested designs is noted by the intersection of circles. For the crossed design, for instance, two main components, p and i , form the intersection, pi . By contrast, the nested design is represented by the i circle being completely enclosed by the p circle.

Any observed score for a single data point can be presented as:

$$X_{\omega} = \mu + \sum_{\omega} v_{\alpha} \quad (1)$$

Fig. 1 Venn diagrams for $p \times i$ and $i : p$ designs.

where ω represents a set of all components in the design, μ is the grand mean in the population, and ν_α pertains to an effect associated with component α . Note that the summation is taken over all components in the design. Provided that all score effects in the model are uncorrelated and random, the variance of observed scores defined in Eq. (1) can be decomposed into independent VCs as

$$\sigma^2(X_\omega) = \sum_{\omega} \sigma^2(\alpha) \quad (2)$$

where $\sigma^2(X_\omega)$ indicates the variance of observed score X_ω . Applying these equations to the example of the crossed design ($p \times i$), any observable score for a person to a single item can be presented as

$$X_{pi} = \mu + \nu_p + \nu_i + \nu_{pi} \quad (3)$$

and consequently,

$$\sigma^2(X_{pi}) = \sigma^2(p) + \sigma^2(i) + \sigma^2(pi) \quad (4)$$

Although not denoted explicitly, ν_{pi} includes the interaction effect between p and i as well as all other errors in the observed score that are not specified by the design (i.e., residual effects). The number of VCs in a model depends on the number of facets and the G study design. The VCs can be estimated using the mean square procedure or a matrix procedure (see appendices B & C in Brennan, 2001a). Both procedures typically yield very similar results unless negative estimates of variance components are encountered. These estimated variance components are the building blocks of generalizability theory analysis and are used in the subsequent D studies.

Infinite universe of generalizability and D studies

As its name implies, generalizability theory enables investigators to generalize a decision about the objects of measurement made from a limited set of responses to a larger (hypothetically infinite) set of measurement conditions of interest. The universe to which the investigators hope to generalize results is referred to as “the universe of generalization” (UG). In general, decisions are made based on an average score over all measurement conditions (e.g., a set of items). Up to this point, however, the VCs estimated in a G study are for single scores (i.e., a response to a single item), not for average scores. To underscore a distinction between the UAO and the UG, an uppercase index (e.g., I for the item facet) is used to represent a facet for D study designs. Unlike CTT where most of the basic results are expressed in terms of the total score metric, generalizability theory employs the mean score metric. Consequently, equations in D study designs are almost always expressed in terms of observed mean scores taken over sets of conditions. For example, a person’s observed mean score over a certain number of items can be decomposed into four effects for the crossed design described previously:

$$X_{pI} = \mu + \nu_p + \nu_I + \nu_{pI} \quad (5)$$

Note that ν_I represents the effect of mean scores over a set of items, not a single item. Note also that the uppercase subscripts are used to denote the mean score metric for D studies.

Universe scores

Under CTT, defining measurement error as the discrepancy between observed scores and true scores requires conceptualization of true scores. The true score in CTT is conceived as an average or expected observed score taken over replications of parallel forms of a measurement procedure. Most basic results in CTT are obtained under the assumptions of classically parallel forms, while some reliability estimates can be derived under essentially tau equivalent or congeneric forms assumptions (Feldt and Brennan, 1989). As discussed later, generalizability theory utilizes the notion of randomly parallel forms. In generalizability theory, a close counterpart to the true score is the universe score. The universe score for a person is defined as the expected value of observed mean scores taken over all random facets in the UG, and is expressed as

$$\mu_p \equiv E_R X_{pR} \quad (6)$$

where R is a set of random facets in the UG. For example, for the $p \times i$ design, R includes the item facet and the expectation is taken over observed scores on different random samples of n'_i items. These random samples of n'_i items are referred to as randomly parallel forms. Note that the D study sample size is denoted using the prime symbol and it needs not be the same as the G study sample size (i.e., n_i). The variance of universe scores over all persons in the population is called universe score variance, which is analogous to true score variance in CTT.

D study variance components (VCs)

Because D studies are concerned with mean scores and not individual scores, the variance components estimated from the G study need adjustments to be used for decision-making for various D study considerations. The D study VCs (i.e., the variance of mean

scores) are found by dividing G study VCs (i.e., the variance of individual scores) by their corresponding sample size. Letting α be any component consisting of $\bar{\alpha}$, then the VC for $\bar{\alpha}$ is

$$\sigma^2(\bar{\alpha}) = \frac{\sigma^2(\alpha)}{\prod_{\alpha \neq p} n'_\alpha} \quad (7)$$

where $\sigma^2(\alpha)$ is the estimated VC from a G study, n'_α denotes the D study sample size associated with α , and the product in the denominator is taken over all components in $\bar{\alpha}$ except for the object of measurement (p). Note that the bar above α indicates that it is a D study effect in the mean-score metric (e.g., for the item facet, $\bar{\alpha} = I$). Application of Eq. (7) to the $p \times I$ design gives:

$$\sigma^2(I) = \frac{\sigma^2(i)}{n'_i} \text{ and } \sigma^2(pI) = \frac{\sigma^2(pi)}{n'_i} \quad (8)$$

It is worth noting that the division is not performed with respect to the object of measurement, p . Consequently, the estimated VC for universe scores $\sigma^2(p)$ remains unchanged for both G and D studies.

Error variances

Two types of error are frequently discussed in generalizability theory. One is called absolute error and is denoted as Δ . Absolute error treats a person's observed mean score as an estimated universe score, and is defined as a discrepancy between a person's observed mean score and universe score. For the $p \times I$ design, for example, absolute error for person p is expressed as,

$$\Delta_p \equiv X_{pi} - \mu_p \quad (9)$$

and its variance for the population of persons, $\sigma^2(\Delta)$, is the sum of all VCs in the D study design except the variance of universe scores:

$$\sigma^2(\Delta) = \sum_{\bar{\alpha} \neq p} \sigma^2(\bar{\alpha}) \quad (10)$$

Consequently, for the $p \times I$ design:

$$\sigma^2(\Delta) = \sigma^2(I) + \sigma^2(pI) \quad (11)$$

Taking a square root of the estimated absolute error variance results in an estimate of the absolute standard error of measurement (SEM).

The second type of error is referred to as relative error, and is denoted δ . Relative error for person p under the $p \times I$ design can be computed as

$$\delta_p \equiv (X_{pi} - \mu_I) - (\mu_p - \mu) \quad (12)$$

As seen in Eq. (12), relative error captures the difference between a deviation of a person's observed mean score X_{pi} from the item mean score, μ_I , for the population and a deviation of a person's universe score μ_p from the grand mean score μ . Due to its reflection of relative status, relative error variance is found as the sum of all VCs that involve p and at least one other index, excluding the components that do not include p in their index:

$$\sigma^2(\delta) = \sum_{p\bar{\alpha}} \sigma^2(\bar{\alpha}) \quad (13)$$

Application of Eq. (13) to the $p \times I$ design yields relative error variance of

$$\sigma^2(\delta) = \sigma^2(pI) \quad (14)$$

An estimate of relative SEM can be obtained by taking the square root of $\sigma^2(\delta)$ in Eq. (14). Relative error is more appropriate to consider when comparing the relative standing or rank ordering of persons' scores. Whereas, absolute error is more appropriately used whenever examinee scores are compared to predetermined criteria such as a cut score.

Reliability-like coefficients

Generalizability theory offers two reliability-like coefficients: a generalizability coefficient, $E\rho^2$, and an index of dependability, Φ . These two coefficients differ with respect to the type of error they incorporate. More specifically, the generalizability coefficient involves relative error variance and is computed as:

$$E\rho^2 = \frac{\sigma^2(p)}{\sigma^2(p) + \sigma^2(\delta)} \quad (15)$$

This equation becomes identical to Cronbach's coefficient alpha under the $p \times I$ design. By contrast, the index of dependability, or a phi coefficient, incorporates absolute error variance and is computed as:

$$\Phi = \frac{\sigma^2(p)}{\sigma^2(p) + \sigma^2(\Delta)} \quad (16)$$

The generalizability coefficient is most appropriate for norm-referenced interpretations of scores whereas the index of dependability is best suited for criterion-referenced or domain-referenced interpretations.

Multivariate generalizability theory

The development of multivariate generalizability theory (MGT) has further advanced the contribution of generalizability theory to the field of measurement (Brennan, 2001a). Imagine a measurement procedure where multiple universe scores exist for an object of measurement and a composite of the universe scores is of primary interest. One such example is a test measuring more than one skills or content areas. Typically, content categories are considered as a fixed facet while items are a random facet. In this case, a person has a universe score associated with each content category, and within each content category, there is a random effects model. A multivariate design is identified as a linkage of these multiple random-effects designs through covariance components.

In MGT, there can be more than one fixed facets. A facet is fixed in the sense that a set of measurement conditions defined by that facet remains the same over replications of a measurement procedure. Specifying the fixed facets is often guided by a table of specifications (Brennan, 2000). Due to this nature, multivariate generalizability theory is sometimes called the table of specifications model (Jarjoura and Brennan, 1982, 1983). In practice, the content areas or cognitive skills outlined in the table specifications are often described as a fixed facet, because every form of the test is expected to include items assessing the same set of content categories or cognitive skills. Then, for each level of different content categories or cognitive skills, any observable score can be represented in a similar fashion to Eq. (1) as a random effects model. Statistical computation and estimation under multivariate designs involving variance and covariance components can be facilitated by the use of matrices. The general estimation approach is similar to the univariate analysis, except now parameters are presented in matrices.

Suppose that the investigator identified two distinct types of items considered to be necessary to assess spelling knowledge: (1) writing down a word after hearing it and (2) completing partially spelled words with the appropriate missing letter(s). Hence, there are two distinct item types, and each corresponds to a distinct level of the fixed facet, item format. If the investigator were to replicate the measurement procedure, items would be randomly sampled from the two aforementioned levels of the fixed facet, item type, and each level would have its own universe of items. The item types are fixed in a sense that every form would include the same types of items over replications. This is a verbal description of a $p' \times i'$ multivariate design. A superscript filled circle associated with the person facet emphasizes that the facet is crossed with the multivariate variable (i.e., item type) whereas a superscript empty circle associated with the item facet indicates that the item facet is nested within the multivariate variable. Under the $p' \times i'$ multivariate design, covariances are only present for the object of measurement (i.e., persons) because examinees respond to both item types.

Because items are nested within item type, all remaining matrices are diagonal as follows:

$$\Sigma_p = \begin{bmatrix} \sigma_v^2(p) & \sigma_{vv'}^2(p) \\ \sigma_{vv'}^2(p) & \sigma_{v'}^2(p) \end{bmatrix} \quad (17)$$

$$\Sigma_i = \begin{bmatrix} \sigma_v^2(i) & \\ & \sigma_{v'}^2(i) \end{bmatrix} \quad (18)$$

$$\Sigma_{pi} = \begin{bmatrix} \sigma_v^2(pi) & \\ & \sigma_{v'}^2(pi) \end{bmatrix} \quad (19)$$

where the notation v and v' is used to refer to different levels of the fixed variable, item type. The elements in the D study matrices Σ_I and Σ_{pI} are obtained by dividing their corresponding element in Σ_i and Σ_{pi} , respectively, in a similar fashion to the univariate analysis. For this particular example, the matrices for universe score, relative error, and absolute error are obtained using the following formulas:

$$\Sigma_\tau = \Sigma_p \quad (20)$$

$$\Sigma_\delta = \Sigma_{pI} \quad (21)$$

$$\Sigma_\Delta = \Sigma_I + \Sigma_{pI} \quad (22)$$

Most often, researchers are interested in results for composite scores. The composite scores are defined as a weighted sum of scores over all levels of a fixed variable. In most applications, weights are determined such that composite scores reflect the relative contribution of each level to the total score in terms of the number of score points. Let w_v be a weight of level v , then the composite universe score is defined as

$$\mu_{pC} = \sum_v w_v \mu_{pv} \quad (23)$$

Composite universe score variance, relative error variance, and absolute error variance for the composite are found using the following formulas, respectively:

$$\sigma_C^2(p) = \sum_v w_v^2 \sigma_v^2(p) + \sum_{v \neq v'} w_v w_{v'} \sigma_{vv'}(p) \quad (24)$$

$$\sigma_C^2(\delta) = \sum_v w_v^2 \sigma_v^2(\delta) \quad (25)$$

$$\sigma_C^2(\Delta) = \sum_v w_v^2 \sigma_v^2(\Delta) \quad (26)$$

Finally, the multivariate generalizability coefficient and phi coefficient for composite scores, are computed by substituting $\sigma_C^2(p)$, $\sigma_C^2(\delta)$, and $\sigma_C^2(\Delta)$ into Eqs. (15) and (16), respectively.

Practical and conceptual considerations in application of generalizability theory

There are several practical and conceptual considerations that an investigator should take into account when using generalizability theory as an analysis framework. This section describes some of those considerations that many researchers might encounter in practice. Then, the following section provides several illustrative examples of how generalizability theory can be used to analyze educational data.

Random versus fixed facets

The essence of generalizability theory lies in the fact that it permits an investigator to identify and isolate facets contributing to measurement error that occurs over replications of a measurement procedure. Inclusion of a certain facet in a design relies on the investigator's identification of potential facets and the decision should be evidenced by the significance of each facet to the precision of the measurement procedure. The investigator not only determines the set of facets, but also defines the UG associated with each of the facets.

Suppose the same conditions appear in every repeated measurement procedure for a certain facet, and the investigator has no interest in generalizing results over the other conditions. Then, we can say that the UG involves a fixed facet. In other words, if there is a fixed number of conditions for the facet in the UG and the D study sample size is equal to the fixed number of conditions in the UG, the facet is fixed. This restricted UG typically leads to increased consistency among observed scores for a given individual but prohibits generalizing results to other conditions of the fixed facet. Some examples of a design that involves a fixed facet are presented later.

Model specification

There are several key questions that must be addressed by the investigator prior to application of generalizability theory to real-world data. For example, it is the investigator's task to answer questions like: What constitutes replications of a measurement procedure? Which facets are random and which are fixed? Are the facets crossed or nested? Answering these questions probably is the most challenging aspect of putting generalizability theory into practice. It is crucial that the investigator identify all potential sources of error, incorporate those major facets in the data collection design, and provide evidence about the importance/contribution of the considered facets to the precision of the measurement procedure. Sometimes, however, practical constraints (e.g., estimation complexity, limited data collection designs) may limit the number of facets that can be considered in a design, or the form of the UG. If this happens, the investigator should be cautious while interpreting results due to the increased bias in analysis invoked by the model specification.

Real data illustration

The next section provides several illustrations of how univariate generalizability theory (UGT) and MGT can be used to analyze educational data. The data used in this section was originally collected in 2015 as part of the Organization for Economic

Cooperation and Development's Program for International Student Assessment (PISA). PISA exams are administered internationally to 15 and 16 year-olds every 3 years and are aimed primarily at assessing students' ability to apply reading, math, and science skills to solve real-world problems (OECD, 2017).

In this section, data from PISA's reading assessment are used first to illustrate univariate single-facet and multi-facet designs. Later, PISA science assessment data is used to demonstrate the use of a multivariate single-facet design. Analyses in this section are based on modified PISA data and therefore, generalizations cannot be made to the operational PISA program. For example, to reduce design complexity, 5 of the 29 reading assessment items were dropped to obtain a balanced design in which each level of a facet has an equal sample size. Furthermore, PISA uses a matrix sampling and administers over 30 forms per content area. However, in this illustration, analyses are carried out using a single form and hence are not representative of the PISA population. Furthermore, PISA assessment results are rarely, if ever, presented for individual students, and instead, focus on country-level reporting. However, each of the illustrations presented next is for designs that specify students as the objects of measurement. Thus, results in this section are purely for illustration purposes.

Univariate $p \times i$ design

The $p \times i$ design is perhaps one of the most straightforward univariate single-facet designs available. In this design, persons or students (p) are the objects of measurement and respond to all items (i). The data used to illustrate this design were collected from students in three countries (i.e., Australia, Brazil, and Spain) who all took the same form of the 2015 PISA reading assessment. A total of 848 examinees were included in the analyses – 331 from Australia, 336 from Brazil, and 181 from Spain. Therefore, we are treating students from these countries as if they belong to the same general population, but an alternative approach would be to carry out analyses within each country. The reading assessment originally contained 29 items, but 5 items were removed, leaving 24 items (i.e., $n_i = 24$). Three D studies were carried out with a varying number of items – the first for a shortened test (i.e., $n'_i = 20$ items), the second for a test of the same length (i.e., $n'_i = 24$ items), and the third for a longer test (i.e., $n'_i = 28$ items). It should be noted that the term “default D study” is often used to refer to a D study that has the same sample sizes as the G study (i.e., $n_i = n'_i$). The software program, GENOVA (Version 3.1; Crick and Brennan, 2001) was used to carry out G and D study analyses. Results for the $p \times i$ design can be seen in Table 1.

VCs from the G study analysis can be seen in the first column of Table 1. These VCs represent the breakdown of the estimated total variance of single examinees on single items, as noted in Eq. (4). There is one VC for each random effect, $\hat{\sigma}^2(\alpha)$, in the design. Note that the VCs and other statistics in Table 1 are denoted with a hat to highlight the fact that they are estimates, not parameters. As seen in Table 1, the VC's for persons and items are roughly equal to each other and roughly 1/3 the magnitude of the VC for the pi interaction. Since PISA reading items are scored dichotomously, the sum of all G study VCs is always smaller than 0.25.

The same design employed in the G study was also carried over to three D studies. VCs for these D studies are representative of the population of PISA examinees and the UG, which, in this example, is made up of randomly parallel forms of the PISA reading assessment. In a D study, decisions about persons are based on their average or mean performance to all n'_i items. $\hat{\sigma}^2(I)$ can be interpreted as the variance of item mean scores, where each mean score comes from a different random sample of n'_i items from the UG. For D studies, capitalized letters are commonly used to indicate results pertaining to mean scores (Brennan, 2001a) whereas in traditional statistics a bar would be used to indicate a mean (i.e., $\bar{X}$).

To obtain $\hat{\sigma}^2(I)$ and $\hat{\sigma}^2(pI)$ for any given D study, one simply divides each G study VC by n'_i , as presented in Eq. (7). For example, $\hat{\sigma}^2(I)$ for the D study with $n_i = 20$ equals $\hat{\sigma}^2(i)/20 = 0.0512/20 = 0.0026$. Universe score variance $\hat{\sigma}^2(\tau)$ for the D studies is the same as its estimated value from the G study, $\hat{\sigma}^2(p)$. Absolute error variance, $\hat{\sigma}^2(\Delta)$ represents the error associated with using a person's actual mean score as an estimate of their universe score. In the $p \times I$ design, absolute error variance for the UG is the

Table 1 G Study and D Study Results for the $p \times I$ Design.

G study		D studies		
$\hat{\sigma}^2(\alpha)$		$n'_i = 20$	$n'_i = 24^a$	$n'_i = 28$
$\hat{\sigma}^2(p) = 0.0471$	$\hat{\sigma}^2(p)$	0.0471	0.0471	0.0471
$\hat{\sigma}^2(i) = 0.0512$	$\hat{\sigma}^2(I)$	0.0026	0.0021	0.0018
$\hat{\sigma}^2(pi) = 0.1539$	$\hat{\sigma}^2(pI)$	0.0077	0.0064	0.0055
	$\hat{\sigma}^2(\tau)$	0.0471	0.0471	0.0471
	$\hat{\sigma}^2(\delta)$	0.0077	0.0064	0.0055
	$\hat{\sigma}^2(\Delta)$	0.0103	0.0086	0.0073
	$E\hat{\rho}^2$	0.8595	0.8801	0.8954
	$\hat{\Phi}$	0.8212	0.8464	0.8653

sum of $\hat{\sigma}^2(I)$ and $\hat{\sigma}^2(pI)$. Relative error variance in generalizability theory is often viewed as an analog to the error variance in classical test theory. Relative error variance, $\hat{\sigma}^2(\delta)$, is concerned with making decisions about a particular examinee, relative to the group of examinees to which that individual belongs. In most cases, individuals are compared to a group mean and that group mean is constant for all individuals. Hence, in the $p \times I$ design, $\hat{\sigma}^2(I)$ does not contribute to $\hat{\sigma}^2(\delta)$ and therefore $\hat{\sigma}^2(\delta)$ is equal to $\hat{\sigma}^2(pI)$. This implies that, unless, $\hat{\sigma}^2(I)$ is zero, absolute error variance is always larger than relative error variance in the $p \times I$ design.

The size of $\hat{\sigma}^2(\Delta)$ and $\hat{\sigma}^2(\delta)$ directly impacts the size of the phi coefficient ($\hat{\Phi}$) and generalizability coefficient ($E\hat{\rho}^2$), respectively. For the $p \times I$ design, the generalizability coefficient and Cronbach's alpha give the same result, both involving relative error variance. Meanwhile, the phi coefficient involves absolute error variance and is more appropriate when examinee performance is being compared to a performance criterion such as a cut score. In the $p \times I$ design, the two reliability-like coefficients are computed using Eqs. (15) and (16). The D Study trends seen in Table 1 are largely predictable based on the equations used to compute D study results. Namely, as n'_i increases, VCs for the random effects (i.e., $\hat{\sigma}^2(I)$ and $\hat{\sigma}^2(pI)$) decrease, error variances decrease, and coefficients increase. These trends can be seen more easily in Fig. 2. Also noticeable from Fig. 2 is the inverse relationship between the size of the error variance and the size of its associated coefficient.

The question of how large coefficients ought to be, is at the discretion of the practitioner or researcher and should be based on the purpose and use of the testing program. As seen in Figs. 2 and 3, the measurement precision gained by going from a 20 item test to a 24 item test is greater than that gained by going from a 24 item test to a 28 item test. Hence, as more and more items are added, measurement precision will tend to improve but at a diminishing rate. It is up to the investigator to weigh the costs and benefits associated with various test lengths.

Univariate $p \times (i : h)$ design

The univariate $p \times (i : h)$ design is similar to the $p \times i$ design except now, items are nested within random passages (h). The same PISA reading data used in the $p \times i$ illustration is also used to illustrate the $p \times (i : h)$ design. However, the PISA reading data used in the $p \times i$ illustration were not modeled faithfully because in reality, those items were nested within reading passages. The PISA data used in this illustration contains 8 passages and each has 3 items associated with it, thus resulting in a total of 24 items. The $p \times (i : h)$ design more faithfully models the table of specifications for the PISA data by incorporating the passage facet into the design. More specifically, $p \times (i : h)$ design consists of three main effects (i.e., $p, h, i : h$) and two interaction effects (i.e., $ph, pi : h$). These effects are easily identified through the use of the Venn diagram as shown in Fig. 4. Also, Fig. 4 provides a comparison between the two designs used for the same set of data.

G study VCs for the $p \times (i : h)$ design can be seen in the first column of Table 2. From the size of the VCs, it can be seen that the VC associated with passages, $\hat{\sigma}^2(h)$, is smaller than the VC associated with items within passages, $\hat{\sigma}^2(i : h)$. This implies that passages are more homogenous than the cluster of items within them.

Three D studies were carried out and each contained a total of 24 items but varied with respect to the number of passages (i.e., 12, 8, or 6) and the number of items nested within each passage (i.e., 2, 3, or 4). Across the three D studies, the total number of items was set equal to the original test length of 24 items. Results for these D studies can be seen in the columns 3 to 5 in Table 2. The size of the D study VCs is directly related to n'_i and n'_h as seen in the following equations:

$$\hat{\sigma}^2(H) = \frac{\hat{\sigma}^2(h)}{n'_h} \quad (27)$$

$$\hat{\sigma}^2(I : H) = \frac{\hat{\sigma}^2(i : h)}{n'_i n'_h} \quad (28)$$

^aIndicates the Default D study.

$$\hat{\sigma}^2(pH) = \frac{\hat{\sigma}^2(ph)}{n'_h} \quad (29)$$

$$\hat{\sigma}^2(pI : H) = \frac{\hat{\sigma}^2(pi : h)}{n'_i n'_h} \quad (30)$$

Universe scores and their variance are defined for the UG and are not impacted by D study sample sizes. Hence, universe score variance for the G study (i.e., $\hat{\sigma}^2(p)$) carries over to any given D study.

For the $p \times (I : H)$ design, $\hat{\sigma}^2(pI : H)$ and $\hat{\sigma}^2(pH)$ contribute to $\hat{\sigma}^2(\delta)$ and $\hat{\sigma}^2(\Delta)$ consists of all the VCs contained in $\hat{\sigma}^2(\delta)$ plus $\hat{\sigma}^2(H)$ and $\hat{\sigma}^2(I : H)$. The generalizability and phi coefficients are computed using Eqs. (15) and (16), respectively. As seen in Table 2, increasing the number of passages had a greater impact on measurement precision than increasing the number of items within passages. This is because we constrained the total number of items to be 24, which thereby resulted in $\hat{\sigma}^2(pI : H)$ and $\hat{\sigma}^2(I : H)$ being equal for all D studies. As seen in Figs. 5 and 6, the scenario with the greatest number of passages (i.e., $n'_h = 12$) led to the smallest error variances and largest coefficients. These findings wouldn't necessarily be expected to hold among D studies with varying test lengths.

Fig. 5 Error variances for three D studies based on the $p \times (I : H)$ design.

Fig. 6 Coefficients for three D studies based on the $p \times (I : H)$ design.

A comparison between D study results from the univariate $p \times i$ design and the current $p \times (i : h)$ design is useful for illustrating the potential consequences of ignoring a facet. First it is important to recall that the G study and D study designs were always identical, meaning that, for example, the $p \times i$ design was used in the G study and the $p \times I$ design was also used in the D study. If one were to compare the facets contained in the $p \times i$ design and $p \times (i : h)$ design, it becomes apparent that passages (h) are ignored in the $p \times i$ design but are taken into account for the $p \times (i : h)$ design. Since the PISA reading exam contains passages, the estimated VCs in the $p \times i$ design are likely biased and this bias will carry over to the D study results such as coefficients and error variances. The inclusion of the passage facet more accurately depicts the exam and results in slightly lower, albeit more defensible, estimates of its measurement precision. This can be seen by comparing error variances and coefficients based on the default D studies from both designs.

Multivariate $p' \times i''$ design

The multivariate $p' \times i''$ design, which is also referred to as the table of specifications model, is similar to a mixed-model univariate $p \times (i : h)$ design with h being fixed (Brennan, 2001a). However, in the $p' \times i''$ design, items are nested within a fixed multivariate variable that has several exclusive levels. Having fixed levels implies that each replication of the measurement procedure will entail the same exact set of levels. In educational contexts, the fixed multivariate variable often represents content domains or item format. Compared to its univariate counterpart, the multivariate design is computationally easier for unbalanced data in which different levels of the fixed facet can have unequal sample sizes. For the $p' \times i''$ design, each level of the fixed facet is represented by a random effects univariate $p \times i$ design. The multivariate design also has an advantage of producing covariance estimates for the linked facet (i.e., object of measurement) as well as estimates of VCs and covariance components for the distinct levels of the fixed multivariate variable.

The PISA science data is used to illustrate this multivariate design. Data in this example were collected from five countries – Australia, Brazil, Spain, Thailand, and Uruguay. Again, examinees were treated as though they belong to the same population but alternatively, analyses could have been carried out within each country. Fifty examinees from each country were retained at random, resulting in a sample size of 250. It should be noted that data manipulation was made for illustrative purposes only, because a balanced design often requires relatively reduced computational complexity and allows for more straightforward interpretations of results over an unbalanced design. The arbitrary manipulation of the data, however, does not necessarily imply lack of capacity of generalizability theory to deal with unbalanced designs.

^aIndicates the default D study.

In the $p' \times i'$ design, item format is modeled as a fixed multivariate variable with two levels: multiple choice (MC) and free response (FR). Persons are considered crossed with respect to item format (and denoted with a closed circle, p') because they respond to both MC and FR items. Items are considered nested within item format, which is denoted using an open circle, i' . Even though both levels of the fixed facet are comprised of a separate $p \times i$ design, these univariate designs are connected through persons because all persons respond to both item formats.

Using the program, *mGENOVA* (version 2.1; Brennan, 2001b), a G study was carried out using the 2015 PISA science assessment data. In total, the data contained item responses from 250 students, each of whom were administered the same form. Analyses were conducted based on 33 items, 28 of which were MC and 5 being FR items (scored 0, 1, and 2). Results from the G study can be seen in the first column in Table 3.

The diagonal matrix elements in Table 3 represent VCs and off-diagonal elements represent covariance components for v and v' . Three D studies were carried out and results for them are presented in columns 2–4 in Table 3. The maximum number-correct score for each D study was 38 points, but the proportion of MC and FR items varied. The v th diagonal element in the D study matrices $\hat{\Sigma}_i$ and $\hat{\Sigma}_{pi}$ was obtained by dividing the v th diagonal element in $\hat{\Sigma}_i$ and $\hat{\Sigma}_{pi}$, respectively, by n_{iv} . Matrices for universe score, relative error, and absolute error were obtained using Eqs. (20)–(22), respectively.

For the PISA science data, composite mean scores were computed as a simple weighted average with weights being proportional to the number of score points associated with each item format. $\hat{\sigma}_C^2(p)$, $\hat{\sigma}_C^2(\delta)$, and $\hat{\sigma}_C^2(\Delta)$ were found using Eqs. (24)–(26), respectively. The multivariate generalizability coefficient and phi coefficient for composite scores, were computed by substituting $\hat{\sigma}_C^2(\tau)$, $\hat{\sigma}_C^2(\delta)$, and $\hat{\sigma}_C^2(\Delta)$ into Eqs. (15) and (16), respectively. When the weights are proportional to item sample size as in this example, the generalizability coefficient for this design is equivalent to the stratified alpha reliability coefficient in CTT (Brennan, 2001a).

For the PISA science data, there was a clear trend in that composite score error variances decreased and composite score coefficients increased as the ratio of MC to FR items increased (Figs. 7 and 8). This finding is not surprising as measurement error for MC items tends to be smaller than that for FR items because FR items generally contain additional measurement error from raters. Relative and absolute error variances for MC and FR item formats can be seen in the diagonal elements in $\hat{\Sigma}_\delta$ and $\hat{\Sigma}_\Delta$, respectively. As long as all VCs > 0 , relative error is consistently smaller than absolute error. In addition, error variances are larger for FR item types compared to MC item types. This can be seen in rows four and five of Table 3 in the diagonal elements of $\hat{\Sigma}_\delta$ and $\hat{\Sigma}_\Delta$, respectively. Univariate coefficients specific to MC and FR items (considered separately) can be computed by substituting the diagonal elements of $\hat{\Sigma}_p$, $\hat{\Sigma}_\delta$, and $\hat{\Sigma}_\Delta$ into Eqs. (15) and (16).

Because the table of specifications plays a central role in all testing programs, it is often desirable to have estimates of measurement precision broken down according to the categories defined within that table. At the same time, there is likely to be equal importance placed on examining psychometric properties for composite scores. The multivariate $p' \times i'$ design is able to evaluate measurement precision at both grain sizes, and for unbalanced data, without much added computational complexity.

Closing remarks

Generalizability theory is a powerful tool to address numerous measurement issues and has been extensively applied to various real-world measurement settings. However, its powerful features come at the cost of added technical complexities, which in turn, has generally limited its use among educational researchers. This article is intended to provide a brief summary of generalizability theory and demonstrate its applicability using real world data. In addition, several important considerations such as what constitutes a random or fixed facet and the important role of the data collection design, are provided. In general, whenever generalizability theory is used, it is imperative for the researcher to model the measurement procedure in its completeness if defensible and accurate results are to be obtained.

This chapter mainly focuses on balanced univariate designs and multivariate designs. Readers might consider the use of an unbalanced univariate design if it better captures the measurement procedure under investigation. However, unbalanced designs often bring complexities for estimating random VCs. A detailed description of unbalanced designs can be found in Brennan (2001a, Chapters 7 and 8).

For readers interested in carrying out their own analyses using generalizability theory, several free computer programs exist. As presented earlier, GENOVA (Crick and Brennan, 2001) can be used for univariate balanced designs, urGENOVA (Brennan, 2001c) for univariate unbalanced designs, and mGENOVA (Brennan, 2001b) for multivariate designs. Also, an R package, gtheory (Moore, 2016), is available for R users. Alternatively, random effects G-study VCs can be estimated using computer packages designed for general statistical analyses such as Varcomp (SAS Institute Inc, 1996). Specific details on how to use of SPSS, SAS, and MATLAB programs for generalizability analyses can be found in Mushquash and O'Connor (2006).

Item response theory

Item response theory (IRT) attempts to mathematically model the probability of an identified response (e.g., correctness, Likert category) based upon the interaction of a person's latent ability and characteristics (e.g., difficulty and discrimination) of an item. IRT has its origins in the work of several key researchers. They include Binet and Simon (1905) and their work on creating an intelligence scale for children. Binet developed the concept of a standardized metric of chronological age and mapped test items on to this scale using pretesting. Thurstone (1925) extended the work of Binet by developing a latent variable scale. Unlike Binet's intelligence scale which could be directly measured, Thurstone proposed an absolute measure of scaling that assumed intelligence at each age was normally distributed but differed in mean and variability. He used response data to map items onto a latent scale using the normal cumulative distribution function. A key contribution of Thurstone was that intelligence could not be directly measured but was latent and had to be inferred from the responses provided by examinees. Several researchers contributed to the concept of a response function of a latent variable (Richardson, 1936; Ferguson, 1943) and estimation of item and ability parameters (Lawley, 1943).

The seminal work can be attributed to Lord (1952) and Rasch (1960). IRT developers tried to overcome the shortfalls of Classical Test Theory (CTT) simplistic linear model, that an observed test score (X) (i.e., the sum of the item scores) is the sum of a latent true score (T) and measurement error (E), where T and E are unobservable. CTT statistics are always dependent on the group of examinees being sampled. Two other shortfalls were that there was no basis for predicting how an examinee would perform on an item and the error score variance is equal for all examinees (Lord et al., 1968; Allen and Yen, 1979).

IRT modeling makes specific assumptions about the test data being studied. The first is that the latent trait(s) being modeled define the complete latent ability space and explain examinee performance. For many tests it is assumed that only one latent ability is required (i.e., unidimensional models). For other tests, the IRT model may require several latent abilities (i.e., multidimensional models). A second assumption is that items are locally independent of each other when conditioning on the latent ability. A third assumption is that an examinees response to an item can be modeled by the item response function. This IRF which depends on the form of the IRT model expresses the probability of getting a score of X (for dichotomous item, IRF can represent the probability of $X = 1$ or $X = 0$) given each level of the latent ability, θ . This probabilistic relationship is independent of the distribution of θ in the population. Most high stakes standardized achievement and licensure tests use IRT to set the scale for reported test results. When fitting IRT models to data it is important to examine the degree to which the assumptions are met, and that the response data provide a reasonable fit the model.

Lord (1952) developed one of the first IRT models in which the interaction between an item and an examinee was expressed in terms of the probability, $p_i(\theta)$, of correctly responding to a dichotomously scored (correct/incorrect) item i , as

$$p_i(\theta) = \text{pr}\{U_i = 1 | \theta\} = \int_{-\infty}^{a_i(\theta - b_i)} \frac{1}{\sqrt{2\pi}} e^{-z^2/2} dz \quad (1)$$

where the latent ability $\theta \in (-\infty, +\infty)$, the discrimination parameter $a_i \in (0, +\infty)$, and the difficulty parameter $b_i \in (-\infty, +\infty)$. Conceptually this formula can best be understood by examining Fig. 1.

Fig. 1 An illustration of the IRT normal ogive model and the resulting ICC.

In this diagram, the top figure illustrates a dashed scatterplot of the theoretical biserial correlation between a latent ability θ , and the artificially dichotomization (where 0 = incorrect vs. 1 = correct response) of proficiency needed to respond correctly to an item. Examinees' whose ability are greater than a threshold γ , will get the item correct. Note, the CTT p -value is the proportion of the marginal distribution above γ . Following linear regression theory, it is hypothesized that at each θ level there is a normal shaped conditional distribution of proficiency, and the proportion of this distribution greater than γ , represents the probability of a correct response. The integration in the formula is determining this proportion of area. When calculated across a range of θ , one would obtain a logistic shaped curve, known as Item Characteristic Curve (ICC), illustrated in the bottom figure (Lord, 1980, p. 30–32). Richardson (1936) first developed the relationship between IRT parameters and CTT item parameters. The steepness of the ICC represents the degree of discrimination, or a -parameter in IRT parameters. This formula was modified to a more tractable logistic form for examinee j on item i , by Birnbaum (1968) and included a third item parameter, $c_i \in [0, 1]$, to account for examinee guessing.

One important contribution of IRT models is the expansion of the concept of measurement accuracy or reliability. In IRT, accuracy of θ estimation is a function of the item parameters and is determined by the Fisher information function described as,

$$I(\theta) = \frac{P_i'^2}{P_i Q_i} \quad (2)$$

where $P_i'^2$ is the squared first derivative of the IRT model with respect θ . For the 3-PL model shown in Eq. (2) the information function is given as

$$I(\theta) = \frac{a_i^2 Q_i}{P_i} \left[\frac{(P_i - c_i)^2}{(1 - c_i)^2} \right] \quad (3)$$

The standard error of estimation of θ is equal to $1/\sqrt{I(\theta)}$. A plot of an information curve and corresponding standard error is displayed in Fig. 2. Unlike the standard error of measurement calculated in CTT which is described as a constant across the ability scale, the IRT $SE(\theta)$ is a function of the item parameters and its value changes across the range of ability. Ideally a licensure or certification test would be composed of items that optimized the test information function (i.e., minimize the measurement error) at the cut score (van der Linden, 2005).

The information function for a test is equal to the sum of the individual item information functions values conditional on θ . The information function is a key element that greatly enhances the utility of IRT. Such applications directly involving the information function include test construction, computer adaptive testing, equating, and differential item functioning (DIF).

Fig. 2 Information (solid) and SE (dashed) curves for an item with $a = 1.0$, $b = 0.0$, and $c = 0.05$.

Review of IRT models

Dichotomous response models

One of the earliest IRT models was developed by [Rasch \(1960\)](#) in which he developed his model to analyze categorical data (e.g., a reading test). The model denotes a response to item I as U_i , where $U_i = 1$ for a correct response and $U_i = 0$ for an incorrect response. The probability of a correct response for an examinee having ability θ can be expressed as

$$p_i(\theta) = \Pr\{U_i = 1|\theta\} = \frac{\theta}{\theta + \delta_i} \quad (4)$$

where $\delta_i \in (-\infty, +\infty)$ is an item difficulty parameter. When transformed to a logarithmic scale the model takes the form,

$$p_i(\theta) = \Pr\{U_i = 1|\theta\} = \frac{1}{1 + \exp(-1.702(\theta - \delta_i))} \quad (5)$$

It should be noted that the 1.702 is a scaling factor to make the function approximate the normal ogive model described in [Eq. \(1\)](#). The greater a person's ability is relative to an item's difficulty the greater the probability of correct response. There is a unique distinction that sets the Rasch apart from other IRT models.

Quite often when parameters are estimated for individuals and items based on response data, their goodness-of-fit can easily be estimated. However, in the strict Rasch perspective ([Andrich, 1988](#); [Wright, 1984](#)) the goal is to find data that fit the model. Thus, items and examinees would be dropped, if they did not fit the model. Another unique feature of this model is that every examinee who has the same number correct score, will have the same ability estimate, regardless of which items they answered correctly. That is an examinee who has the five easiest items correct will get the same ability estimate as an examinee who answered the five most difficult items correctly.

The leading program for Rasch model and accompanying statistics is the program Winsteps ([Linacre, 2019](#)). The RWinsteps ([Albano and Babcock, 2019](#)) is a developed R package, which makes the use of Winsteps more convenient.

ICCs for the Rasch model never intersect. In [Fig. 3](#) the ICC's labeled A and B represent Rasch ICCs with parameters ($a = 1$, $b = -1.1$) and ($a = 1$, $b = -0.8$), respectively.

In the two-parameter logistic (2PL) model a discrimination parameter, a_i , is added to the model. This parameter allows the slopes of the ICCs to vary from item to item. The model is written as

$$p_i(\theta) = \Pr\{U_i = 1|\theta\} = \frac{1}{1 + \exp(-1.702a_i(\theta - b_i))} \quad (6)$$

The a -parameter is proportional to the slope of the ICC at the point of inflexion (i.e., $a = \text{slope}/0.425$). In the Rasch model all a 's are set to 1.0, whereas in the one-parameter logistic (1PL) model in which the a -parameter for all items is fixed to the mean a across all items. For both the 1PL/Rasch model and the 2PL model, the b value equals the θ -value at which $p_i(\theta) = 0.5$. In [Fig. 3](#), curves C and D are 2PL ICC's that have parameters ($a = 0.8$, $b = 0.0$) and ($a = 1.3$, $b = 0.3$), respectively. If the response model is logistic and the n item parameters are known, then the weighted item score s , where

$$s = \sum_i^n a_i u_i \quad (7)$$

is a sufficient statistic for estimating an examinee latent ability θ .

Fig. 3 ICCs for the 1PL (A,B), 2PL (C,D) and 3PL (E,F) models.

In some testing scenarios guessing is assumed to occur. In this scenario the appropriate model to describe the data may be the 3PL model, given as

$$p_i(\theta) = \Pr\{U_i = 1|\theta\} = c_i + \frac{(1 - c_i)}{1 + \exp(-1.7a_i(\theta - b_i))} \quad (8)$$

where c_i is the guessing parameter. The guessing parameter is the lower asymptote of the 3PL ICC and represents the probability of an examinee randomly guessing and getting an item correct. In this model the slope of the ICC at the point of inflexion is $0.425a(1-c)$. Note that when $c = 0$, the 3PL is equivalent to the 2PL model. The two 3PL ICC in Fig. 3 are E and F with parameters $(a = 0.9, b = 1.3, c = 0.15)$ and $(a = 1.1, b = 1.7, c = 0.22)$, respectively.

Because there is an indeterminacy for the latent θ scale, it is usually assumed that the latent abilities are distributed as standard normal distribution or $N(0,1)$ and thus the latent abilities are rescaled to $N(0,1)$ after initial estimates are obtained. Estimation programs that are used to estimate the parameters for the dichotomous models include BILOG (Mislevy and Bock, 1982), PARSCALE (Muraki and Bock, 1993) and flexMIRT (Cai, 2022).

Polytomous response models

The dichotomous response models above are used under situations when the responses are scored dichotomously. In other words, when one answers one item, the response can only be scored correctly (1) or incorrectly (0). However, depending on the items and how the items are scored, there might be more score categories other than 0 and 1. For instance, depending on the rubric used, the response can be credited partially, which leads to more than two score categories. Therefore, in contrast to dichotomous response models, to model data with more than two score categories, the polytomous response models were developed. Please note that polytomous response models with modeling data containing only two score categories is equivalent to dichotomous response models. The following section introduces the most popular polytomous response models.

Partial credit model and generalized partial credit model

The generalized partial credit model (GPCM) is an extension of the partial credit model. The partial credit model (PCM) (Masters, 1982) was designed for items in which there was increasing credit given for responses $b = 1, \dots, m_{ih}$. This model was a variation of the Rasch model requiring items to be equally discriminating. It was formulated as

$$p_{ib}(\theta) = \Pr\{U_i = b|\theta\} = \frac{\exp\left(\sum_{h=1}^b (\theta - b_{ih})\right)}{\sum_{b=1}^{m_i} \exp\left(\sum_{h=1}^b (\theta - b_{ih})\right)} \quad (9)$$

Muraki (1992) created the generalized partial credit model (GPCM) in which item discrimination parameters, α_i , were free to vary. In GPCM the probability of getting response b ($b = 1, \dots, m_{ih}$) in the h th score category for item i is:

$$p_{ib}(\theta) = \Pr\{U_i = b|\theta\} = \frac{\exp\left(\sum_{h=1}^b \alpha_i(\theta - \delta_{ih})\right)}{\sum_{b=1}^{m_i} \exp\left(\sum_{h=1}^b \alpha_i(\theta - \delta_{ih})\right)} \quad (10)$$

where $\delta_{ih} = \delta_i - d_h$, and $\alpha_i \in (0, +\infty)$, is a slope parameter for item i , δ_{ih} represents the transition location parameter between the h th category and the $h-1$ category and m_i denotes number of response categories for item i . The item-category parameter δ_{ih} can be further decomposed into two parts: the item-location parameter δ_i , and the threshold parameter d_h for each category d_h . Note, that item i containing m_i response categories has m_i-1 item-category parameters, because the first item-category parameter is arbitrarily set to 0 ($\delta_{i1} \equiv 0$). The location parameter δ_i represents the overall difficulty of item i . The threshold parameter d_h represents the relative difficulty of category h compared to other categories within an item. The summation of d_h of a same item is constrained to equal to 0 to overcome the issue of indeterminacy:

$$\sum_{h=2}^{m_i} d_h = 0 \quad (11)$$

From the equation, one can readily see that when $\theta = \delta_{ih}$, $P_{ih}(\theta) = P_{i,h-1}(\theta)$, thus, the ICC for h th category on item i will intersect with the ICC for $h-1$ st category. When $\theta > \delta_{ih}$, $P_{ih}(\theta) > P_{i,h-1}(\theta)$, meaning subjects with ability θ is more likely to fall into h th category compared to $h-1$ st category. When $\theta < \delta_{ih}$, $P_{ih}(\theta) < P_{i,h-1}(\theta)$, subjects with ability θ is more likely to fall into $h-1$ st category compared to h th category. An example of the category characteristic curves for a given set of parameters is shown in Fig. 4.

The marginal maximum likelihood estimation (MMLE) method is commonly used for GPCM estimation. Other estimation methods have also been developed, such as weighted maximum likelihood estimation (Penfield and Bergeron, 2005) and Bayesian estimation (Li and Baser, 2012).

Previous research has proposed 500 as the minimal required sample size for GPCM. Test length has little influence with respect to model-data fit (Naumenko, 2014). GPCM item parameter estimation can be conducted in the following developed software including PARSCALE (Muraki and Bock, 1993) or MULTILOG (Thissen et al., 2003) computer programs. There are also developed R packages which can conduct parameter estimation for GPCM, such as *mirt* (Chalmers, 2012) and *ltm* (Rizopoulos, 2006).

Graded response model

In contrast to GPMC/PCM, which focuses on the probability of obtaining adjacent score categories, the GR model specifies the probability of obtaining category score x_i or higher versus responding in lower category scores. Samejima (1969, 1972) developed the Graded Response Model (GRM) which includes a family of mathematical models for *ordered polytomous categories*. This family of models includes the general case (Samejima, 1969), the homogeneous (Samejima, 1973), and the heterogeneous case (Samejima, 1995). Similar to the GPCM mode, the GR model also contains a discrimination parameter for each item. The examinee responses to item i are categorized into graded $m_i + 1$ categories (m_i is the number of categories boundaries). The model can be expressed as

Fig. 4 GPCM category characteristic curves for an item with parameters $\alpha = 0.95$, $\delta = 0.48$, $d_1 = 0.0$, $d_2 = 0.64$, $d_3 = -0.40$ and $d_4 = -0.24$.

$$p_{ib}(\theta) = \begin{cases} 1 & \text{for } b = 1 \\ \Pr\{U_i \geq b|\theta\} & \text{for } b = 2, \dots, m_i \\ 0 & \text{for } b > m_i. \end{cases} \quad (12)$$

$P_{ib}(\theta)$ for $b = 2, \dots, m_i$ is the 2PL model expressed in Eq. (4). The response functions for these categories can be expressed as

$$p_{ib}(\theta) = p_{ib}(\theta) - p_{i(b+1)}(\theta) \quad (13)$$

When there are only two possible response categories (i.e., correct and incorrect), the GRM reduces to the 2PL model.

GRM has been used in various assessment and test contexts, including physician clinical competence assessment (de Ayala et al., 1992), questions for psychological/non-cognitive assessment (Lubbe and Schuster, 2019), educational writing tests, classroom assessment, personality inventories and computerized adaptive tests. GRM has always attracted researchers' attention. For example, recently Falk (2020) proposed an extension of GRM called Monotonic Polynomial Graded Response Model, which results in more flexible category response functions.

The GRM can be estimated using various developed standard software such as MULTILOG (Thissen et al., 2003) and PARSCALE (Muraki and Bock, 1993). DeMars (2002) and Yavuz and Hambleton (2017) compared different kinds of software to estimate the GRM.

Nominal model

The nominal response model was developed by Bock (1972) for polytomous items which have unordered response categories. It has been used for situations as: (1) item option analysis for multiple-choice items, (2) response option analysis for a survey or attitude instrument, and (3) rater judgments, etc. (De Ayala, 2013). The model can be written as

$$p_{ib}(\theta) = \Pr(U_i = b|\theta) = \frac{\exp(\alpha_{ib}(\theta - \gamma_{ib}))}{\sum_{b=1}^{m_i} \exp(\alpha_{ib}\theta - \gamma_{ib})} \quad (14)$$

where $P_{ib}(\theta)$ is the probability of choosing the response category b_{ib} , $b = 1, \dots, m_i$, and the slope parameter, α_{ib} , and the intercept parameter γ_{ib} have the same interpretation as the discrimination and difficulty parameters in the 2PL model. The model is not identified in a sense that the addition of any constant to either all of α_{ib} 's or all of γ_{ib} 's yield different parameter sets but the same value of $p_{ib}(\theta)$. To rectify this problem, identification constraints are imposed such that $\alpha_{i0} = \gamma_{i0} = 0$. Despite an item having a nominal format, the values for the intercept parameter do imply and order. An example of the category response curves for a given set of parameters is illustrated in Fig. 5.

Fig. 5 Category characteristic curves for a nominal model.

Marginal maximum likelihood estimation of both item parameters and latent traits are often used for Nominal model's parameter estimation, which is described in detail in Baker and Kim (2004). The parameter estimation can also be conducted using computer software such as PARSCALE (Muraki and Bock, 2003), MULTILOG (Thissen et al., 2003), FlexMIRT (Cai, 2022), or R packages including "mirt" (Chalmers, 2012). De Ayala and Sava-Bolesta (1999) suggested that a ratio of the sample size to number of parameters (SSR) as 10:1 can yield reasonable accurate item parameter estimation when the latent trait is normally distributed. However, DeMars (2002) found that a key in estimation is the ratio of sample size to number of categories, not SSR.

Generalized graded unfolding model

Like the nominal IRT model, generalized graded unfolding model (GGUM) (Roberts et al., 1998), was also developed for self-report attitude questionnaires that measures subjects' disagreement-agreement to attitude statement. What makes attitude questionnaire special to educational data is that subjects with opposite attitudes can give same responses. For a same statement, one subject may think it is too conservative and disagree with it; another subject may think it is too liberal and disagree with it. GGUM model is designed to handle this special condition. In GGUM, data can be either binary or polytomous (e.g., a Likert scale).

Let a_i and δ_i denote the discrimination and the location on attitude continuum for statement i . θ_j denotes the location on the attitude continuum for person j . Let τ_{ik} denotes threshold parameters of category k for statement i , and Z_i denotes the observed response to statement i . The probability of person j falls in z th observed category on statement i is given by the following equation:

$$p_{iz}(\theta_j) = \Pr(Z_i = z | \theta_j) = \frac{\exp\left\{a_i \left[z(\theta_j - \delta_i) - \sum_{k=0}^z \tau_{ik}\right]\right\} + \exp\left\{a_i \left[(M - z)(\theta_j - \delta_i) - \sum_{k=0}^z \tau_{ik}\right]\right\}}{\sum_{w=0}^C \left\{ \exp\left\{a_i \left[w(\theta_j - \delta_i) - \sum_{k=0}^w \tau_{ik}\right]\right\} + \exp\left\{a_i \left[(M - w)(\theta_j - \delta_i) - \sum_{k=0}^w \tau_{ik}\right]\right\} \right\}} \quad (15)$$

where: C is the number of observable response categories minus 1, and M is calculated by $2C + 1$. The response z , can take any integer values range from $[0, C]$ and $z = 0$ corresponds to strongest level of disagreement and $z = C$ refers to strongest level of agreement.

The latent attitude continuum of the GGUM model is on the $\theta - \delta$ scale, instead of the traditional θ scale, to contain both the direction and magnitude of the distances between subject's attitude location and statement's location. Since subjects on opposite location have same probability to choose same category, the shape of ICC curve of GGUM model is symmetrical for each category.

GGUM is an extension of GPCM. Parameters of GGUM also has similar constrains as in the GPCM. Statement discrimination parameters are constrained to be all positive ($a_i > 0$); threshold τ_{i0} is constrained to be 0 ($\tau_{i0} \equiv 0$), and

$$\sum_{k=0}^C \tau_{ik} = 0 \quad (16)$$

The GGUM equation is a reparameterization of two GPCM models, one for the lower part of the attitude continuum, the other for its symmetric opposite counterpart representing the upper part of the attitude continuum. Specifically, the separate subjective response curves, SRC, are combined to form the Objective Response Curves ORC curves for one category are illustrated in Fig. 6 and the ORC for a complete set of categories is shown in Fig. 7.

Like the GPCM, the parameters in GGUM are estimated using the marginal maximum likelihood estimation. Statement parameters a_i , δ_i , and τ_{ik} are first solved via the iterative EM algorithm. Subject attitude parameter θ_j is then estimated based on a_i , δ_i , and τ_{ik} .

The minimal required sample size for GGUM is 500. Simulation studies have shown that a sample size of 750 is able to obtain reasonably well estimates for all parameters. Test length and its interaction with sample size have relatively less influence on

Fig. 6 GGUM Subject Response Category, SRC, curves (left) and Objective Response Category, ORC, curves (right) for a disagree category.

Fig. 7 GGUM category characteristic curves for an item with parameters $\tau_0 = 0$; $\tau_1 = -1.3$; $\tau_2 = -0.7$; $\tau_3 = -0.3$; $\tau_4 = 0.0$; $\tau_5 = 0.3$; $\tau_6 = 0.7$; $\tau_7 = 1.3$; $a = 0.95$, $b = 0.48$, $d_1 = 0.0$, $d_2 = 0.64$, $d_3 = -0.40$ and $d_4 = -0.24$.

parameter estimates (Roberts et al., 1998). The GGUM parameters can be estimated using the computer program GGUM2004 (Roberts et al., 2006). Wang et al. (2015) developed a MCMC GGUM program that uses Markov chain Monte Carlo (MCMC) approach. Recently, an R package named “GGUM” is also available (Tendeiro and Castro-Alvarez, 2019).

Multidimensional models

A two-dimensional extension of the 2-PL unidimensional model for dichotomously scored items multidimensional compensatory (M2PL) model (Reckase, 2009), which can be expressed as

$$p_i(\theta_1, \theta_2) = \Pr(u_i = 1 | \theta_{1j}, \theta_{2j}) = \frac{1.0}{1.0 + e^{-(a_{1i}\theta_{1j} + a_{2i}\theta_{2j} + d_i)}} \quad (17)$$

where a_{1i} and a_{2i} represent the discrimination parameters for item i on dimension one and two, respectively; and, θ_{1j} and θ_{2j} denote the latent abilities for subject j . In this model, item difficulty for each dimension is indeterminate, thus there is only one overall difficulty parameter for item i , d_i . Similarly, a guessing parameter, c_i , could be added to this model (see Eq. 6), but affects only the overall probability and would not be broken down for each dimension. Thus, if this model were extended to n -dimensions, there would be an a_{ni} and θ_{nj} parameter for each dimension, but only one d_i .

This model is described as “compensatory” because the abilities weighted by their an item’s respective discrimination parameters are additive in the logit. Thus, being “low” on one ability can be compensated by being “high” on the other ability. The degree of compensation depends on the a -parameters and is maximal when $a_{1i} = a_{2i}$.

Another way to express the interaction between the two traits is in a noncompensatory fashion as shown in the noncompensatory MIRT (Reckase, 2009) given as

$$p_i(\theta_1, \theta_2) = \Pr(u_i = 1 | \theta_{1j}, \theta_{2j}) = \left[\frac{1.0}{1.0 + e^{-1.7(a_{1i}\theta_{1j} - b_{1i})}} \right] \left[\frac{1.0}{1.0 + e^{-1.7(a_{2i}\theta_{2j} - b_{2i})}} \right] \quad (18)$$

In this model, for a given item i each dimension has discrimination parameters, a_{1i} and a_{2i} , as well as difficulty parameters, b_{1i} and b_{2i} . Also θ_{1j} and θ_{2j} denote the latent abilities on the two dimensions for subject j . This model is essentially the product two 2PL unidimensional IRT models, one for each dimension. The multiplicative nature of this model also implies that being “low” on one dimension cannot be compensated by being “high” on the other dimension. That is, the overall probability of correct response is never greater than the largest probability of the two dimensions. Specifically, if the first dimension (θ_1) p -component is 0.20 and the second dimensional p -component (θ_2) was 1.0, the over all probability of correct response would only be 0.20.

Researchers have developed numerous ways to illustrate and represent items, item and test surfaces and information in a multidimensional context (Ackerman, 1994, 1996; Reckase, 2009; Ackerman, Ma & Ip, 2019). Examples of compensatory and non-compensatory surfaces and contour plots are illustrated in Fig. 8. Many of the previously reviewed models do have multidimensional extensions. However, MIRT models are not currently being used in high stakes testing or licensure and certification testing. MIRT model parameters can be estimated using such programs as NOHARM (Fraser and McDonald, 1988), TESTFACT (Wilson et al., 1984), and flexMIRT (Cai, 2022).

One variation of MIRT models is the diagnostic classification model (DCM). These models share some of the same scaling intent as MIRT, but with more fine-grained, dichotomous attributes rather than continuous latent scales, dichotomous “loadings” (i.e., a Q-matrix), and no explicit covariance structures that relate the latent attributes to one another. The Q-matrix is the quintessential component in any DCMs because it represents an empirical hypothesis about the attribute structure that can be tested. DCMs are

Fig. 8 Compensatory ($a_1 = 1$, $a_2 = 1$, $d = 0$) and noncompensatory ($a_1 = 1.0$, $a_2 = 1.0$, $b_1 = 0.0$, $b_2 = 0.0$) surfaces and corresponding contour plots.

also considered special case of constrained latent class models (LCMs), which are developed to provide more accurate and informative mastery profile for respondents at a fine diagnostic grain size. Two seminal sources detailing DCM models, their use and their estimation are [Rupp et al. \(2010\)](#), and [von Davier and Lee \(2019\)](#).

Parameter estimation of IRT models

The item response model does not allow for a closed form expression to estimate either the item parameters or the latent ability. There are, however, several estimation procedures to get around this limitation involving the likelihood function $L(u|\theta, a, b, c)$. These include joint maximum likelihood estimation, marginal maximum likelihood estimation, and Markov chain Monte Carlo estimation.

Joint maximum likelihood estimation

One of the major problems in estimating IRT item and ability parameters is that there is no closed form expression to estimate each parameter. One proposed approach proposed by [Birnbaum \(1968\)](#) was a two-stage joint maximum likelihood estimation (JMLE) procedure. Fitting a 3PL model to a test having n items and N examinees requires the estimation of $3n + N$ parameters. In each stage the estimation is centered around the likelihood function given as

$$\ln L(u|\theta, a, b, c) = \sum_{j=1}^N \sum_{i=1}^n [u_{ij} \ln p_{ij} + (1 - u_{ij}) \ln q_{ij}] \quad (19)$$

where u_{ij} for item i by examinee j is the scored 0/1 response and p_{ij} is the 3PL model shown in Eq. (6). In the first stage, the item parameters are estimated assuming the examinee abilities are known. Usually, a standardized raw test score would serve as an initial ability estimate for each examinee. In the second stage, the examinee abilities are estimated assuming the item parameters are known. The item parameter estimates used in the second stage are the estimates obtained from the first stage. In each stage Newton-Raphson iteration is used to maximize the log of the likelihood function. The two-stage process would iteratively run and terminate when the change in each parameter estimate from successive stages is less than a given convergence criterion (e.g., 0.01).

A graphical example of a second stage estimation for an examinee has a item response vector of [10110] for five items whose Items parameters were $\hat{a} = [0.94, 1.4, 0.88, 1.0, 0.9]$, $\hat{b} = [0.94, 1.4, 0.88, 1.0, 0.9]$, $\hat{c} = [0.0, 0.0, 0.0, 0.0, 0.0]$. The graph of $\ln L$ is shown in Fig. 9 along with the four Newton Raphson iteration approximations. The initial estimate was $\hat{\theta} = 0$. It can be seen that convergence to the maximum likelihood θ -estimate takes only a few iterations before the difference between successive iterations becomes negligible, with the final estimate being $\hat{\theta} = 0.74534$.

Note this process can be carried out for multidimensional models below. In Figs. 10 and 12 is a graphical example of three Newton-Raphson iterations for a two-dimensional model for an examinee with a response vector of [00100] and the estimated two-dimensional discrimination parameters are $\hat{a} = [\{0.94, 0.0\}, \{0.0, 1.4\}, \{0.88, 1.0\}, \{1.0, 0.9\}, \{0.08, 1.5\}]$ and the vector of difficulty parameters are $\hat{d} = [1.2, 0.8, -0.4, 0.2, 0.9]$. The final MLE (θ_1, θ_2) ability estimate $(-0.63, -1.28)$ is cross validated using the contour plot of the log likelihood surface.

Several researchers including Hambleton and Swaminathan (1985), Baker and Kim (2004), Finch and French (2019) have detailed joint maximum likelihood estimation.

Marginal maximum likelihood estimation

Marginal maximum likelihood estimation (MMLE) which is a technique used for item parameter estimation. In the MMLE technique it is assumed that examinees represent a sample from the population in which the latent ability is distributed according to a known density function (e.g., $N(0,1)$). Bock and Lieberman (1970) provided a solution in which they integrated over the ability distribution which removed the ability parameters from the likelihood function allowing for the item parameters to be estimated in the marginal distribution. A further improvement on the MMLE was the EM algorithm developed by Bock and Aitkin (1981). The EM algorithm is an iterative procedure that enables the maximum likelihood estimation of the item parameters by maximizing the formed marginal likelihood function (Thissen, 1982; De Ayala, 2013; van der Linden, 2018). One advantage of MMLE is that because the persons are integrated out from the estimation process, increasing sample size does not affect the estimation process as it would in using JMLE. Person parameters, θ 's, are usually calibrated using Newton-Raphson iteration after the item parameter estimation results achieve the satisfactory of the model fit.

Bayesian priors are frequently employed in the estimation of IRT item parameters to constrain the range of the parameter estimates as well. Common priors include a normal distribution for both ability and b parameter estimates, lognormal distribution for a -parameter estimates, and beta distribution for c -parameters estimates. Examples of these priors are illustrated in Fig. 11.

Fig. 9 An illustration of Newton-Raphson iteration example for a five-item test.

Fig. 10 An illustration of two-dimensional compensatory model Newton-Raphson MLE estimation.

An example of an application of using a normal prior is illustrated in Fig. 12. In this figure, on the left the likelihood MLE would be $+$. Using a $N(0,1)$ prior we can create a posterior distribution, which is the likelihood $\times$ prior, and then estimate the MLE from the posterior (figure on the left).

Markov chain Monte Carlo

Another approach to IRT model parameter estimation is Markov chain Monte Carlo (MCMC) sampling. MCMC has been successfully applied in various IRT and IRT-related settings. For instance, [Fox \(2010\)](#) extended the data-augmentation-based MCMC for normal ogive models to hierarchical IRT models. Other IRT related models using MCMC includes testlet models ([Bradlow et al., 1999](#)), models for test compromise ([Segall, 2002](#); [Shu, 2010](#)). There are numerous existing standard software which can conduct MCMC algorithm including WinBUGS ([Lunn et al., 2009](#)), OpenBUGS ([Spiegelhalter et al., 2012](#)), [Stan Development Team \(2019\)](#) and JAGS ([Plummer, 2012a,b](#)).

Fig. 11 Example prior distributions used for dichotomous IRT models.

Fig. 12 Graphical illustration of Bayesian ability estimation.

Goodness-of-fit

It is important to note that no model will fit a given set of response data perfectly. To assess how closely estimated parameters fit both at the item and test level there are standard procedures that can be performed. For example, fit statistics designed specifically for the Rasch model (Wright and Masters, 1983; Linacre, 2003) are infit and outfit. Infit is inlier oriented and is sensitive to the pattern of responses to item targeted on the examinee. Outfit is outlier-sensitive and more sensitive to responses to items₁ with difficulty far from the person.

Another approach is to examine the accuracy of model predictions versus what we observed in the observed data. At the item level we can examine residuals for item j . That is, dividing the θ -scale into k -intervals (usually where the number of subjects in the interval is greater than 5) and determining the difference between observed proportion correct $p_i^*(\bar{\theta}_i)$, and the predicted (expected) probability, $p_i(\bar{\theta}_i)$, based on estimated parameters. The concept of item model misfit is illustrated in Fig. 13.

One commonly used approach to assess the fit of an item is Yen's Q_1 statistic, Yen (1984). This statistic is computed for an item i by dividing the θ -scale from $[-4,4]$ into K cells, where the number of examinees in each cell >5 and then comparing the observed proportion correct with the expected proportion correct. Specifically,

$$Q_{1i} = \sum_{j=1}^K \frac{N_j (O_{ij} - E_{ij})^2}{E_{ij} (1 - E_{ij})} \quad (20)$$

where: N_j is the number of examinees in cell j , O_{ij} is the observed proportion of examinees in cell j that respond correctly to item i , and E_{ij} is $p_i(\bar{\theta})$, the probability of correct response (e.g., Eq. 6) given the estimated item parameters and $\bar{\theta}$ is the mean or median $\hat{\theta}$ of the N_j examinees. Q_1 is distributed as a χ^2 statistic with K minus the number of estimated item parameters.

Fit statistics and graphical measures of fit are provided by such programs as BILOGMG (Mislevy and Bock, 1990). Approaches for conducting goodness-of-fit investigations for checking model assumptions are outlined in Hambleton and Swaminathan (1985).

Fig. 13 Example of misfitting 2PL model and accompanying residual.

Introduction

Item response theory (IRT) can be viewed minimally as a set of psychometric models for categorical item-level response data (Cai et al., 2016). It can also be viewed from the statistical angle as a set of interrelated discrete multivariate statistical models and methods that help address the needs arising out of item analysis, test development and validation, linking and equating, test assembly and adaptive testing, and test scoring and reporting (Thissen and Steinberg, 2009). Cai et al. (2016) also demonstrated IRT's usefulness in data analysis for large-scale educational assessments and in evaluation studies using experimental or quasi-experimental designs. IRT has a long history that can be traced at least to Thurstone's (1925) effort on locating Binet test questions on the chronological age scale (see Bock, 1997). Since the publication of Lord and Novick's (1968) *Statistical Theories of Mental Test Scores*, IRT gradually became an active research area. IRT is now one of the most important modern psychometric methodologies, and is broadly applied to data from educational assessments and other areas such as clinical outcome assessments.

IRT models describe the relationship among the items' psychometric properties, item responses, and individual latent variable(s) theorized to influence the item responses. The formulation of IRT models relies on careful descriptions of the individual response process, assumptions about the latent variable distributions, and the critical *conditional independence* assumption to turn the psychometric models into multivariate statistical models. The conditional independence assumption states that conditional on the latent variable(s), responses to items are independent. Stated in another way, the items are correlated because of the influence of the latent variables.

In the context of traditional unidimensional IRT models, the conditional independence assumption implies that the dependence or covariation among observed item responses is solely attributable to the presence of one single continuous latent variable. This unidimensionality assumption is often violated in practice because many constructs in social and behavioral sciences are inherently multifaceted (e.g., quality of life), and observed item responses may also be influenced by more than one latent variables because of features of test design (e.g., passage-based reading tests or language tests).

Multidimensional item response theory (MIRT) models naturally extend traditional unidimensional IRT models by including more than a single latent variable in model formulation. MIRT models can also be viewed as factor analysis models for categorical item level data (Wirth and Edwards, 2007). In this article, we present recent developments in MIRT and major applications of MIRT models.

From unidimensional IRT models to MIRT models

Let us consider the two-parameter logistic (2PL) model, a classic unidimensional IRT model for items scored in 2 categories (e.g., correct/incorrect, symptom present/not present, endorse/not endorse). For a generic item i , the item response is a Bernoulli (0–1) random variable U_i . As its name suggests, the 2PL model (Eq. 1) uses two item parameters to describe how the conditional probability of the correct response for item i changes as a function of the latent variable θ , which characterizes individual differences on the dimension of interest. The latent variable is often, though not always required, assumed to follow a standard normal distribution, $\theta \sim \mathcal{N}(0, 1)$.

$$P(U_i = 1|\theta) = \frac{1}{1 + \exp[-(c_i + a_i\theta)]} \quad (1)$$

The slope/discrimination parameter a_i is the increase in the logit of the correct response probability that corresponds to one unit increase in θ . The intercept parameter c_i is the logit when $\theta = 0$. Fig. 1A shows the item characteristic curve (ICC) for an item with $a_i = 1.5$ and $c_i = 0.5$, whereas Fig. 1B presents the y -axis in logits. A higher a_i value suggests that the item can better differentiate individuals with similar θ values. The classical item difficulty parameter b_i , i.e., the θ point at which $P(U_i = 1|\theta)$ is 0.5, can be computed as $b_i = -c_i/a_i$.

The item i can best differentiate individuals whose θ values are close to its 50–50 point. That is to say, it provides the most psychometric information in the range near b_i along the θ continuum. The amount of information an item can provide depends on its discriminating power. Under the 2PL model, the item information function, denoted by $\mathcal{I}(\theta)$, is given by the formula,

$$\mathcal{I}(\theta) = a_i^2 P(U_i = 1|\theta)[1 - P(U_i = 1|\theta)] \quad (2)$$

Fig. 2 shows the item information functions of three hypothetical items with $a_1 = 0.75$, $c_1 = 0.5$, $b_1 = -0.67$; $a_2 = 1.5$, $c_2 = 1$, $b_2 = -0.67$; and $a_3 = 0.75$, $c_3 = 1$, $b_3 = -1.33$. Having the same slope parameter, the relatively easy item (item 3) provides more

Fig. 1 Unidimensional two-parameter logistic (2PL) model. Item characteristic curve (ICC) for a 2PL model when $a = 1.5$, and $c = 0.5$.

Fig. 2 Item information functions of three hypothetical items. Item parameters are respectively $a_1 = 0.75$, $c_1 = 0.5$, $b_1 = -0.67$; $a_2 = 1.5$, $c_2 = 1$, $b_2 = -0.67$; and $a_3 = 0.75$, $c_3 = 1$, $b_3 = -1.33$.

information in the lower- θ range than the difficult item (item 1). The more-discriminating item (item 2) provides more information than the less-discriminating item (item 1). Statistically, the item information function also indicates the precision of θ estimates, and its reciprocal $1/\mathcal{I}(\theta)$ equals the asymptotic variance of the maximum likelihood estimates (MLEs) of the latent variable θ , the square root of which is also referred to as the *Standard Error of Measurement*.

In MIRT models, a D -dimensional latent variable vector $\boldsymbol{\theta} = (\theta_1, \dots, \theta_d, \dots, \theta_D)$ is used instead of the scalar θ . Two classes of MIRT models, *compensatory* and *noncompensatory* models, can be distinguished by the nature of how the latent variables are combined to influence the item response probability.

In the more widely used *compensatory* models, the response probability depends on a linear combination of the latent variables inside the logit (Eq. 3).

$$P(U_i = 1|\boldsymbol{\theta}) = \frac{1}{1 + \exp[-(c_i + a_{i1}\theta_1 + \dots + a_{iD}\theta_D)]} \quad (3)$$

The slope parameter a_{id} indicates the rate of change in the logit-probability with respect to θ_d . The relative item difficulty that corresponds to dimension d is $-c_i/a_{id}$, which is interpretable as the 50–50 point for the response probability on the dimension corresponding to θ_d , while holding $\boldsymbol{\theta}$ at 0 on all other dimensions. The multidimensional generalization of the a_i in the unidimensional model is the so-called multidimensional discrimination index (MDISC; Reckase and McKinley, 1991), which is often denoted by A_i . The MDISC is the overall measure of an item's ability to distinguish individuals in the D -dimensional latent space, and is defined as the following,

$$A_i = \sqrt{\sum_{d=1}^D a_{id}^2} \quad (4)$$

The important point here is that with compensatory models, a low value on one or more of the latent variables can be offset by high values of other latent variables. Fig. 3 shows the item response surface (instead of a curve as in a unidimensional model) of an item when $D = 2$ with $a_{i1} = 1.5$, $a_{i2} = 0.75$ and $c_i = 0.5$. When θ_1 approaches the lower extreme of the latent continuum (i.e., $\theta_1 = -3$), there is still a substantial correct/positive response probability when θ_2 is high.

Analogous to the unidimensional case, where the item information varies over levels of θ , the item information in MIRT models is defined as a function of $\boldsymbol{\theta}$'s position in the D -dimensional latent space,

$$\mathcal{I}(\boldsymbol{\theta}) = \left(\sum_{d=1}^D a_{id} \cos \alpha_d \right)^2 P(U_i = 1|\boldsymbol{\theta}) [1 - P(U_i = 1|\boldsymbol{\theta})] \quad (5)$$

where α_d indicates the angle between the d th axis and a line from the origin to the $\boldsymbol{\theta}$ point, and is introduced to accommodate the difference in slopes of a point on different dimensions.

In a *noncompensatory* model for dichotomous data, the probability of a correct response is the product of probabilities of D unidimensional models (Eq. 6).

$$P(U_i = 1|\boldsymbol{\theta}) = \prod_{d=1}^D \frac{1}{1 + \exp[-(c_{id} + a_{id}\theta_d)]} \quad (6)$$

Fig. 3 Compensatory multidimensional item response theory model. Item response curve for a compensatory MIRT model when $a_1 = 1.5$, $a_2 = 0.5$, and $c = 0.5$.

Each of the unidimensional models includes a slope parameter a_{id} and an intercept parameter c_{id} . This can lead to estimation challenges. Noncompensatory MIRT models are appropriate when an item can be hypothesized to involve several distinct parts that depend on different latent variables in the response process. The reader is referred to sources such as Reckase (2009) for more in-depth discussions about compensatory and non-compensatory MIRT models. Again, though not required, θ is often assumed to follow a multivariate normal distribution $\theta \sim \mathcal{N}(\mathbf{0}, \Sigma)$. Elements of Σ show how the latent variables covary.

MIRT models

We focus on the compensatory MIRT models (i.e., Thurstonian item factor analysis models; Bock et al., 1988; Bock and Aitkin, 1981) and show how different MIRT models can be formulated for items with two response categories before moving on to polytomous data. Due to space constraints, we present in detail only the multidimensional extension of Samejima's (1969) graded response model (GRM) for ordered polytomous responses. Discussions about multidimensional extensions of the generalized partial credit model and partial credit model can be found in Yao and Schwarz (2006), Kelderman and Rijkes (1994), and Reckase (2009). At the end of this section, we introduce the nominal response model (NRM; Bock, 1972), which does not assume ordered categories, and review a new parameterization (Thissen et al., 2010; Thissen and Cai, 2016) that allows the generalization of the NRM to the case of MIRT.

To provide a context of discussions, let us consider an assessment with four sections that respectively measure four domains of students' language proficiency (reading, listening, writing, and speaking). The English Language Proficiency Assessment for the 21st Century (ELPA21; Cai and Hansen, 2018) is a concrete example. Let us assume that the test includes both multiple choice (MC) items, which have two scored categories (i.e., correct and incorrect), and constructed response (CR) items, which have more than two ordered score categories to reflect partial credit scoring of test taker performance using a rubric. The four sections in the assessment can be treated as four separate tests and modeled with four sets of unidimensional IRT models, as is often done in practice. However, by doing so, the correlations among the four domains of language proficiency are ignored, to the detriment of psychometric evaluations and validation studies, as well as limiting the range of possibilities in score reporting. Depending on the assumption regarding how latent variables influence observed item responses, different MIRT models can be specified.

Correlated-factors MIRT models

One of the many sensible ways to formulate a MIRT model in our context is shown in Fig. 4, in which items (squares) in the four sections measure respectively four correlated latent variables (circles) that represent students' (correlated) proficiencies in reading, listening, writing, and speaking. With this correlated-factors MIRT model, one can obtain estimated proficiency levels on each of the four latent variables (i.e., four scaled scores) simultaneously. Below we present how the 2PL model, the three-parameter logistic (3PL) model, and the GRM (Samejima, 1969) can be extended to their MIRT counterparts.

2PL model correlated factors extension

Let $\theta = (\theta_1, \dots, \theta_4)'$ denote a 4-dimensional vector whose elements represent students' proficiencies in reading, listening, writing, and speaking. Items may load on a single domain, or cross domains, reflecting the interactive language modality that requires more than one domain-based skills. The probability of answering a dichotomous item correctly can be specified as a function of θ and the item parameters,

$$P(U_i = 1 | \theta) = \frac{1}{1 + \exp[-(c_i + a_{i1}\theta_1 + a_{i2}\theta_2 + a_{i3}\theta_3 + a_{i4}\theta_4)]} = \frac{1}{1 + \exp[-(c_i + \mathbf{a}_i'\theta)]} \quad (7)$$

Fig. 4 Correlated-trait MIRT model. The squares in the figure represent items, while the circles represent latent variables measured with the assessment, which are reading (*R*), listening (*L*), writing (*W*) and speaking (*S*). The single-headed arrows from the latent variables to the items indicates that levels of latent variables impact responses to items. The double-headed arrows show that the latent variables are correlated with each other.

in which $\mathbf{a}_i = (a_{i1}, a_{i2}, a_{i3}, a_{i4})'$ is a vector of slope/discrimination parameters, and c_i is the intercept parameter.

As mentioned earlier, the correlated factors extension of the 2PL model is closely related to the categorical confirmatory factor analysis (CCFA) model. Parameter estimates of $\mathbf{a}_i$ and c_i can be easily converted to parameters of the CCFA model, and vice versa (Takane and De Leeuw, 1987; Wirth and Edwards, 2007; Cai, 2010a). The CCFA model assumes that each individual possesses a latent item score x_i^* , reflecting his/her position on a normally-distributed latent response scale. It is also assumed that for the item i (which has 2 categories), there exists a threshold parameter τ_i , so that

$$U_i = \begin{cases} 1, & x_i^* \geq \tau_i, \\ 0, & x_i^* < \tau_i. \end{cases} \quad (8)$$

The covariance structure of the latent scores can then be modeled as

$$\Sigma^* = \Lambda^* \Phi^* \Lambda^{*'} + \Psi^* \quad (9)$$

where Σ^* represents the covariance between latent item scores, Λ^* denotes the factor loading matrix, Φ^* is the covariance matrix of latent common factors, and Ψ^* is the unique variance matrix. The asterisk indicates that both sides of Eq. (9) are latent.

Suppose each of the four domains in the example (reading, listening, writing, and speaking) is measured by 2 unique items. The factor loading matrix Λ^* , whose rows correspond to items and columns correspond to common latent factors, is a 8×4 matrix

$$\Lambda^* = \begin{bmatrix} \lambda_1^* & 0 & 0 & 0 \\ \lambda_2^* & 0 & 0 & 0 \\ 0 & \lambda_3^* & 0 & 0 \\ 0 & \lambda_4^* & 0 & 0 \\ 0 & 0 & \lambda_5^* & 0 \\ 0 & 0 & \lambda_6^* & 0 \\ 0 & 0 & 0 & \lambda_7^* \\ 0 & 0 & 0 & \lambda_8^* \end{bmatrix}$$

If estimates of $\mathbf{a}_i$ and c_i were obtained, elements of Λ^* can be computed as

$$\lambda_i^* = \frac{a_i/1.702}{\sqrt{1 + (a_i/1.702)^2}} \quad (10)$$

and the threshold parameter τ_i is

$$\tau_i = \frac{-c_i/1.702}{\sqrt{1 + (a_i/1.702)^2}} \quad (11)$$

in which 1.702 is a traditionally-used scaling constant that puts logistic parameters on a normal ogive metric.

3PL model correlated factors extension

For an MC item, it is possible that a student with lower proficiencies could still answer it correctly by guessing. The 3PL model is an extension of the 2PL model and uses a non-zero lower asymptote to account for the impact of guessing on item characteristics. Its multidimensional extension may be expressed as

$$P(U_i = 1|\boldsymbol{\theta}) = g_i + (1 - g_i) \frac{1}{1 + \exp[-(c_i + \mathbf{a}_i' \boldsymbol{\theta})]} \quad (12)$$

in which $\mathbf{a}_i$ and c_i continue to be the slope vector and intercept parameters, respectively, and g_i is the lower asymptote (pseudo-guessing) parameter (Bock et al., 1988).

GRM correlated factors extension

Muraki and Carlson (1995) proposed the multidimensional extension of Samejima's (1969) GRM. For an item with K ordered categories, e.g., an item in the CR section, a set of cumulative probabilities are specified,

$$P(U_i \geq 0|\boldsymbol{\theta}) = 1$$

$$P(U_i \geq 1|\boldsymbol{\theta}) = \frac{1}{1 + \exp[-(c_{i,1} + \mathbf{a}_i' \boldsymbol{\theta})]}; \quad (13)$$

$$P(U_i \geq K-1|\theta) = \frac{1}{1 + \exp[-(c_{i,K-1} + \mathbf{a}_i'\theta)]}$$

$$P(U_i \geq K|\theta) = 0$$

such that the probability that the item response U_i is in category k , $k = 0, \dots, K-1$ can be computed as the difference between two adjacent cumulative probabilities,

$$P(U_i = k|\theta) = P(U_i \geq k|\theta) - P(U_i \geq k+1|\theta) \quad (14)$$

The bifactor/testlet models

In addition to assessing the proficiencies in the language domains, the goal of the assessment may be to provide an overall evaluation of students' language proficiency. That is to say, instead of reporting four domain scores with the correlated-trait model, one overall score may be desired. In this new context, the bifactor model (Holzinger and Swineford, 1937; Cai et al., 2011) can be useful.

The bifactor model captures the factorial structure of many educational and psychological tests that consist of items selected from domains (or multifaceted subdomains) and aim to measure a more general construct when assembled together. Specifically, the bifactor model assumes that there is one general latent variable (the general factor) that contribute to the covariance among all items and several latent variables that are group-specific that explain additional dependence among items in the same domain/sub-domain (Fig. 5). In addition to assuming that each item loads on the general factor and at most one group-specific factor, it further assumes that the group factors are conditionally independent given the general factor.

Restricted versions of the bifactor model exist and the most prominent example is the testlet response model (Bradlow et al., 1999). Specifically, to obtain a testlet response model from the bifactor model, one can constrain an item's loading on the group-specific factor to be proportional to its loading on the general factor (Rijmen, 2010). Another well-known restricted version of the bifactor model is the second-order model (Fig. 6), which assumes conditionally-independent group-specific factors and

Fig. 5 Bi-factor model. The latent variable G represents students' overall language proficiency, and impacts responses to all items. The latent variables R^* , L^* , W^* , and S^* impact only items that load on them. Note, the asterisk indicates that R^* , L^* , W^* , and S^* are different from R , L , W , and S in Fig. 4.

Fig. 6 Second-order factor model. In the second-order factor model, a second-order factor HO is introduced to explain the covariance between group-specific factors.

introduces a second-order factor to explain the covariance between the group-specific factors. The second-order factor model is equivalent to the testlet response model and can be obtained from the bifactor model by imposing proportionality constraints as well (Rijmen, 2010; Yung et al., 1999).

2PL model bifactor extension

Gibbons and Hedeker (1992) developed the bifactor item response model for binary data with the normal-ogive (probit) link function. The logistic counterpart, which is a direct extension of the 2PL model is

$$P(U_i = 1|\theta) = \frac{1}{1 + \exp[-(c_i + a_i\eta + \beta_{id}\xi_d)]} \quad (15)$$

for an item that belong to domain $d = 1, \dots, 4$. The latent variable $\theta = (\eta, \xi_1, \xi_2, \xi_3, \xi_4)'$ consists of one general latent variable η and four domain-specific latent variables ξ_d . For example, if there were 8 items and each domain is measured by 2 unique items, the pattern of item slopes can be represented as a 8×5 matrix as follows

$$\begin{bmatrix} a_1 & \beta_{11} & 0 & 0 & 0 \\ a_2 & \beta_{21} & 0 & 0 & 0 \\ a_3 & 0 & \beta_{32} & 0 & 0 \\ a_4 & 0 & \beta_{42} & 0 & 0 \\ a_5 & 0 & 0 & \beta_{53} & 0 \\ a_6 & 0 & 0 & \beta_{63} & 0 \\ a_7 & 0 & 0 & 0 & \beta_{74} \\ a_8 & 0 & 0 & 0 & \beta_{84} \end{bmatrix}$$

As shown in Eq. (15) and the matrix above, for any item, only two factors (i.e., the general factor and the group factor it loads on) are involved, even though the total latent dimensionality of the model is five. The key advantage of the bifactor pattern is in computational savings for item parameter estimation, to be discussed in **Estimation of MIRT models and scoring individuals** section.

GRM bifactor extension

Gibbons et al. (2007) developed a bifactor item response model for graded response data, which may be useful for the CR items. We can express the bifactor extension of the GRM as follows:

$$\begin{aligned} P(U_i \geq 0|\theta) &= 1 \\ P(U_i \geq 1|\theta) &= \frac{1}{1 + \exp[-(c_{i,1} + a_i\eta + \beta_{id}\xi_d)]}; \\ P(U_i \geq K-1|\theta) &= \frac{1}{1 + \exp[-(c_{i,K-1} + a_i\eta + \beta_{id}\xi_d)]} \\ P(U_i \geq K|\theta) &= 0, \end{aligned} \quad (16)$$

and

$$P(U_i = k|\theta) = P(U_i \geq k|\theta) - P(U_i \geq k+1|\theta).$$

The two-tier model

In the assessment context described above, the reading and listening domains focus on the test taker's receptive language modality, while the writing and speaking sections focus on the productive language modality. If proficiencies in these language modalities are of primary interest, we may utilize the two-tier model (Cai, 2010c) for data analysis and scaled score estimation. The two-tier model includes two types of latent variables. The primary latent variables (e.g., students' receptive and productive proficiencies) are in the first tier, and group-specific latent variables in the second tier (Fig. 7). The primary latent variables are analogous to the general factor in the item bifactor model, and they can be correlated, while the specific latent variables are conditionally independent given the primary latent variables, similar to the group-specific factors in a bifactor model, accounting for residual covariance among non-overlapping subsets of items above and beyond the primary dimensions. The standard correlated-factors MIRT model and the various bifactor models discussed in the previous subsections can all be viewed as special cases of the two-tier model.

Fig. 7 Two-tier model. The *REC* and *PRO* are the two primary latent variables and represent students' receptive and productive language proficiencies. The *R'*, *L'*, *W'*, and *S'* are the specific latent variables. Note when there is no specific latent variables, the two-tier model becomes a correlated-trait MIRT model. When there is only one primary latent variable, it becomes a bi-factor model.

In the example depicted in Fig. 7, we have a total of 6 latent variables: $\theta = (\eta_1, \eta_2, \xi_1, \xi_2, \xi_3, \xi_4)'$. The extension of the 2PL model in the two-tier modeling framework is

$$P(U_i = 1|\theta) = \frac{1}{1 + \exp[-(c_i + a_{i1}\eta_1 + a_{i2}\eta_2 + \beta_{id}\xi_d)]} \quad (17)$$

for an item that belongs to domain indexed by latent variable d . Eq. (17) states that the probability of endorsing an item depends on both primary latent variables and the specific latent variable on which the item loads. For example, if there were 8 items and each domain is measured by 2 items, the pattern of item slopes can be represented as a 8×6 matrix as follows

$$\begin{bmatrix} a_{11} & 0 & \beta_{11} & 0 & 0 & 0 \\ a_{21} & 0 & \beta_{21} & 0 & 0 & 0 \\ a_{31} & 0 & 0 & \beta_{32} & 0 & 0 \\ a_{41} & 0 & 0 & \beta_{42} & 0 & 0 \\ 0 & a_{52} & 0 & 0 & \beta_{53} & 0 \\ 0 & a_{62} & 0 & 0 & \beta_{63} & 0 \\ 0 & a_{72} & 0 & 0 & 0 & \beta_{74} \\ 0 & a_{82} & 0 & 0 & 0 & \beta_{84} \end{bmatrix}$$

Cai (2010c) illustrated the use of the two-tier model in the context of longitudinal IRT modeling, complex educational assessments, and response style analysis, with demonstrations of how other IRT models can be extended to the two-tier case.

An aside: multidimensional NRM

In contrast to the GRM, Bock's (1972) nominal response model (NRM) does not require ordered categorical data. The original formulation of the NRM is based on the multinomial logit link function:

$$P(U_i = k|\theta) = \frac{\exp(a_{ik}\theta + c_{ik})}{\sum_{j=0}^{K-1} \exp(a_{ij}\theta + c_{ij})} \quad (18)$$

which states that the conditional probability that the response U_i falls in category $k = 0, \dots, K-1$ depends on the latent variable θ and item parameters $\mathbf{a}_i$ and $\mathbf{c}_i$. Due to the translational invariance of the multinomial logit, not all elements of $\mathbf{a}_i$ and $\mathbf{c}_i$ are simultaneously estimable. For identification purposes, constraints on item slopes and intercepts are necessary, e.g., $\sum_{k=0}^{K-1} a_{ik} = \sum_{k=0}^{K-1} c_{ik} = 0$. As Bock (1972) showed, these constraints can be implemented by reparameterization using various contrast matrices akin to those used in analysis of variance, i.e.,

$$\mathbf{a}_i = \mathbf{T}_a \boldsymbol{\alpha}_i, \quad \mathbf{c}_i = \mathbf{T}_c \boldsymbol{\gamma}_i,$$

where the T_a and T_c are contrast matrices of dimension $K \times (K-1)$ and α_i and γ_i contain the estimable contrasts for slopes and intercepts. There are altogether $2(K-1)$ free parameters in the unidimensional NRM.

Thissen et al. (2010) presented a new parameterization of the NRM to facilitate its extension to the case of MIRT. Specifically, the new parameterization separates a_{ik} (in Eq. 18), the $(k+1)$ -th element of the slope parameter, into two components: an overall slope a_i and scoring function parameters for category k , s_{ik}

$$P(U_i = k | \theta) = \frac{\exp[s_{ik}(a_i\theta) + c_{ik}]}{\sum_{j=0}^{K-1} \exp[s_{ij}(a_i\theta) + c_{ij}]} \quad (19)$$

Dropping the i subscript for a moment, the following identification constraints,

$$s_0 = 0, \quad s_{K-1} = 0 = K - 1, \quad \text{and} \quad c_0 = 0 \quad (20)$$

are implemented by reparameterizing $\mathbf{s}$ and $\mathbf{c}$ using contrast matrices

$$\mathbf{s} = T_s \alpha, \quad \mathbf{c} = T_c \gamma, \quad (21)$$

where α takes on the role of scoring function contrasts. Thissen et al. (2010) demonstrated the model with a Fourier contrast matrix augmented with a linear column. In this new parameterization, $K-2$ elements of α are freely estimated, $K-1$ intercept contrasts are free, and the overall slope a is freely estimated. In other words, the number of free parameters is identical to the original model in Eq. (18). Thissen et al. (2010) also showed that popular IRT models for polytomous items such as the rating scale (RS; Andrich, 1978) model, the partial credit model (Masters, 1982), and the generalized partial credit (GPC; Muraki, 1992) model can be seen as constrained cases of the NRM, with this new parameterization.

The key benefit of this new parameterization lies in the fact that it offers a smooth path to extend the NRM to a MIRT model by expanding both the scalar θ and the overall slope a of item i into vectors,

$$P(U_i = k | \theta) = \frac{\exp[s_{ik}(\mathbf{a}'_i \theta) + c_{ik}]}{\sum_{j=0}^{K-1} \exp[s_{ij}(\mathbf{a}'_i \theta) + c_{ij}]} \quad (22)$$

where θ is the vector of latent variables, $\mathbf{a}_i$ is a vector of item slopes of the same dimension as θ . This model is nominal in the sense that for the linear combination of latent variables ($\mathbf{a}'_i \theta$), the category may not be ordered. A more general form of the model (Thissen and Cai, 2016) is,

$$P(U_i = k | \theta) = \frac{\exp\{[\mathbf{a}_i \circ \mathbf{s}_{ik}]' \theta + c_{ik}\}}{\sum_{j=0}^{K-1} \exp\{[\mathbf{a}_i \circ \mathbf{s}_{ij}]' \theta + c_{ij}\}} \quad (23)$$

in which $\circ$ denotes the Schur product, $\mathbf{s}_{ik}$ is the $(k+1)$ -th column of a $D \times K$ scoring function matrix $\mathbf{S}_i$, whose rows correspond to latent dimensions and columns correspond to item categories. By using the $\mathbf{S}_i$ (instead of the K -dimensional vector $\mathbf{s}_i$ as in Eq. 22), scoring functions are allowed to vary across latent dimensions.

Estimation of MIRT models and scoring individuals

The two major uses of IRT are item analysis and test scoring (Thissen and Steinberg, 2009). The former task requires statistical tools to obtain item parameters, and the latter involves the computation of individual scores (and standard errors) along the latent continua. From a statistical point of view, the two steps corresponds to the standard procedure in empirical Bayes inference. Item analysis produces structural parameter estimates, typically with maximum marginal likelihood, and the test scoring step produces scale scores, which are empirical Bayes estimates of the random effects/latent variables.

Using notation established above, the conditional likelihood of response pattern $\mathbf{u} = (u_1, \dots, u_i, \dots, u_I)$ can be written as

$$L_{\omega}(\mathbf{u} | \theta) = P\left(\bigcap_{i=1}^I U_i = u_i | \theta\right) = \prod_{i=1}^I P(U_i = u_i | \theta) = \prod_{i=1}^I \prod_{k=0}^{K-1} [P(U_i = k | \theta)]^{\chi_k(u_i)} \quad (24)$$

where we have utilized the conditional independence assumption such that the joint response pattern probability factors into a product, and $\chi_k(u_i)$ is an indicator function that equals to 1 if and only if u_i is equal to k , 0 otherwise. The likelihood is a function of ω , which contains all the item parameters and any other structural parameters (e.g., means and covariances of the population distribution). The marginal likelihood is an integral of the conditional likelihood over the population/prior distribution $h(\theta)$ of the latent variables θ :

$$L_{\omega}(\mathbf{u}) = \int \prod_{i=1}^I P(U_i = u_i | \theta) h(\theta) d\theta \quad (25)$$

The marginal likelihood, when maximized over ω , leads to the marginal maximum likelihood estimates of the item parameters.

In this section, we outline approaches of estimating MIRT model parameters and methods of scoring individuals. The test scoring section is more abbreviated, because the methods are parallel to those for estimating θ in unidimensional IRT models. We refer interested readers to [Thissen and Wainer \(2001\)](#) for details.

Bock-Aitkin EM algorithm

[Bock and Aitkin \(1981\)](#) proposed a procedure to obtain maximum likelihood estimates (MLEs) of IRT model parameters based on [Dempster et al.'s \(1977\)](#) expectation-maximization (EM) principle. The idea is to treat observed item responses as incomplete data and latent variables as missing data so that they together form complete data. The Bock-Aitken EM algorithm alternates between the *Expectation* step and the *Maximization* step. In the *E*-step, the integrals in the conditional expected complete data log-likelihood is approximated with numerical quadrature. In the *M*-step, the conditional expected complete data log-likelihood is maximized to yield updated item parameters. The two steps are repeated until the sequence of parameter estimates stabilize (convergence).

The item parameter estimates based on the Bock-Aitkin EM algorithm is often considered the gold standard in IRT. However, a major drawback of the EM algorithm is the “curse of dimensionality.” As the number of latent variables increases linearly, the total number of quadrature points grows exponentially. Thus, the Bock-Aitkin EM algorithm can be cumbersome for MIRT models.

Metropolis-Hastings Robbins-Monro (MH-RM) algorithm

[Cai \(2008, 2010a,b\)](#) proposed the Metropolis-Hastings Robbins-Monro (MH-RM) algorithm for maximum likelihood estimation in IRT models. The dominating insight of the MH-RM algorithm is that were the values of the latent variables (i.e., missing data) known, the complete likelihoods maximization would be easy. The MH-RM algorithm combines the Metropolis-Hastings (MH; [Metropolis et al., 1953](#); [Hastings, 1970](#)) sampler with the Robbins-Monro (RM) stochastic approximation algorithm ([Robbins and Monro, 1951](#)). Each iteration of the MH-RM algorithm involves three steps. In the *Stochastic Imputation* step, the MH sampler is used to simulate draws of the latent variable scores from their posterior predictive distribution to form complete data. In the *Stochastic Approximation* step, the gradient ascent directions of the observed data log-likelihood is computed indirectly from the Monte Carlo average of the gradient of the complete data log-likelihood, invoking the Fisher's Identity ([Fisher, 1925](#)). In the *Robbins-Monro Update* step, parameters are updated through the RM algorithm, which appropriately handles the Monte Carlo noise introduced in earlier step and guarantees pointwise convergence of the sequence of parameter estimates.

The MH-RM algorithm has been successfully applied in many IRT contexts (e.g., [Monroe and Cai, 2014](#); [Chalmers and Flora, 2014](#); [Yang and Cai, 2014](#)). It outperforms the Bock-Aitkin EM algorithm for high-dimensional problems in efficiency because it does not involve numerical quadrature.

Markov chain Monte Carlo (MCMC) approach

Markov chain Monte Carlo (MCMC; [Tierney, 1994](#)) involves drawing random samples with the help of a Markov chain from target distributions that are otherwise difficult to sample from. When applied in the fully Bayesian context, the target distribution is the joint posterior distribution of parameters. The samples from the Markov chain offer simple MCMC-based procedures have been proposed to estimate MIRT models (e.g., [Béguin and Glas, 2001](#); [Kim and Bolt, 2007](#); [Edwards, 2010](#); [Babcock, 2011](#)), building upon previous work on MCMC estimation of unidimensional IRT models (e.g., [Albert, 1992](#); [Patz and Junker, 1999a,b](#)). While applying MCMC algorithms, prior distributions of model parameters have to be specified. However, this has to be done with caution since the specification of priors will impact parameter estimates, even *non-informative* prior.

Scaled score based on response patterns

Once the items parameters are estimated, we can plug them into the MIRT model and make predictions of the latent variable θ based on an individual's responses to all I items, $\mathbf{u}$. Suppose the maximum marginal likelihood estimate is $\hat{\omega}$. From the Bayes rule, the posterior distribution of the latent variables is

$$P_{\hat{\omega}}(\theta|\mathbf{u}) = \frac{L_{\hat{\omega}}(\mathbf{u}|\theta)h(\theta)}{\int L_{\hat{\omega}}(\mathbf{u}|\theta)h(\theta)d\theta} = \frac{L_{\hat{\omega}}(\mathbf{u}|\theta)h(\theta)}{L_{\hat{\omega}}(\mathbf{u})} \quad (26)$$

where structural (item) parameters have been replaced with their maximum marginal likelihood estimates. Based on the posterior, we can compute the *Expected A Posteriori* (EAP) and *Maximum a Posteriori* (MAP) estimates by computing the mean and mode of the posterior. If a stochastic algorithm such as the MH-RM algorithm is used, multiple imputation or plausible values of θ may also be obtained ([Mislevy et al., 1992](#)).

Summed score to IRT scaled scores

An estimate of θ can be also obtained from the posteriors conditional on observed summed scores (Thissen and Wainer, 2001). The computation typically relies on the Lord-Wingersky algorithm (Lord and Wingersky, 1984), which is a recursive algorithm for computing summed score based likelihoods. A summed score to IRT scale score conversion table can be produced at the end, facilitating the use of IRT scoring without the more complex computation involved in IRT scoring based on response patterns. Cai (2015) extended the Lord-Wingersky algorithm to the case of bifactor and two-tier MIRT models.

Example applications and future directions

Educational measurement

Educational assessments routinely measure multi-faceted constructs, and subscores are of particular interest. Several approaches can be used to obtain subscores, including approaches based on classical test theory (CTT), unidimensional IRT and MIRT. Subscores derived through the MIRT approach are more accurate than those derived by CTT (Haberman and Sinharay, 2010). It is also shown that the MIRT-based approach provides more reliable subscores, overall scores (Yao, 2010), and more accurate classification information (Yao and Boughton, 2007).

MIRT models are also applied to longitudinal data to measure students' change over time. For example, Lockwood and Castellano (2015) proposed to apply the MIRT framework as an alternative to quantile regression to estimate the popular student growth percentile (SGP; Betebenner, 2009). The SGP is used in many states to help understand a student's academic progress by comparing his/her growth in scale score to the growth of students with similar prior year performance on standardized assessments (e.g., a student with SGP 75 indicates this student outperforms 75% of students who scored similarly in prior years). Monroe and Cai (2015) presented a straightforward method for estimating SGP reliability in the MIRT framework and evaluated how it is heavily impacted by the correlation between prior and current year score distributions.

te Marvelde et al. (2006) applied multidimensional generalized partial credit models to longitudinal survey data to measure students' change in three aspects as related to school effectiveness ("well-being at school", "academic self concept", and "attentiveness in the classroom"). Paek et al. (2016) pointed out the equivalence between MIRT models and longitudinal IRT models and elaborated how to analyze longitudinal categorical item response data with MIRT models. An MIRT-based approach is also proposed to monitor ability changes in computerized practice environments (Park et al., 2019).

Clinical outcomes assessment

A clinical outcome assessment (COA) typically evaluates health-related endpoints for clinical care, research, and trials. MIRT models, especially the bifactor model, play an important role in assessment development, short form construction, and refinement (e.g., Gibbons et al., 2009; DeWitt et al., 2011; Hansen et al., 2014; Shadel et al., 2014).

In COA, self-report questionnaires involving Likert-type items (e.g., strongly disagree, disagree, neutral, agree, strongly agree) are often used. Participants' response styles (e.g., tendencies to use endpoints, or the middle point), along with their genuine symptom severity levels, are both reflected in the item responses. One area in which MIRT can contribute further information is in explicit response style modeling. Falk and Cai (2016) proposed an approach based on the multidimensional NRM. This approach is further extended to multilevel data (Ju and Falk, 2019).

Future directions

In this article, we have reviewed recent developments in the MIRT literature. We conclude this article with discussions of future directions of research on MIRT. MIRT models discussed in this article assume that the individuals are uncorrelated. However, in educational and clinical settings, data usually exhibit multilevel structures with nesting or cross-classification. Thus, MIRT models for hierarchical and cross-classified data need to be studied. Current MIRT models also assume fixed item effects (i.e., fixed item parameters) and random person effects (i.e., θ follow a multivariate normal distribution). A new class of MIRT models with random item effects can be developed and would lead to new applications such as item bank development. In addition, we have assumed that all latent variables are continuous in this article. If the latent variables in MIRT models become discrete—we obtain the so-called diagnostic classification models (DCMs; Rupp et al., 2010), which have important research and practical implications in educational measurement.

Typically, the focus of measurement is on obtaining an estimate of a person's location on a construct. In contrast, explanatory measurement seeks to provide an explanation of the measurement. Thus, compared with the common measurement approaches, explanatory measurement offers extra opportunities for the explanation and validation of the measurement result. Explanation is a core activity of science (Hand, 2016) and measurement is considered an important preliminary condition for explanatory research. Explanatory measurement brings this perspective of explanation into the conceptualization of the statistical models used in measurement, so that the measurement can help lead to scientific advancements by shaping further explanatory research.

In psychology and the educational sciences, and in science in general, constructs play a crucial role. The measurement of constructs is often based on sum scores across a set of items that are formulated to reflect the targeted construct. The constructs can be cognitive abilities or non-cognitive variables, whether stable or not, and they may represent typical performance or maximum performance. In a statistical model used in measurement, the item responses are modeled to be a probabilistic function of an underlying latent variable that is conceptualized as the representation of a construct. Hence the estimates of an individual's latent variable value on a chosen scale function as measurements; that is, as estimates of the construct (e.g., cognitive abilities, etc.).

The common measurement practice can be characterized as follows:

1. A set of items is thought of as generating a set of indicators of the construct. This is the basic transduction in the measurement situation (Mari et al., 2021).
2. The measurements are averages of, or more complex functions of, the item responses. The scores obtained from the item responses indicate the average level of the responses (as in a sum score or a weighted average), or the scores reflect the most likely latent variable value given the responses depending on the model. Scores are summaries of the overall level of the responses (higher or lower), whether model based or not.
3. First measure, then validate. The conceptual link between items and construct is the basis to develop or select items, but the conceptual link needs to be empirically validated. In this separate step, one should test whether the item responses are in line with the conceptualized link using internal validity criteria such as internal consistency based reliability, internal structural consistency (e.g., difficulty order, factor loadings, etc.), goodness of fit of the model and/or the items, and using external validity criteria such as the relationship with external variables, the validity of which will be dependent on the assumed validity of the external structure (nomothetic span).
4. Measurement is descriptive. The scores indicate the level of the construct (e.g., a cognitive ability) without explaining why it is as high or low as it is found to be. To answer the deeper question of "why?," one needs to rely on external variables.

Explanatory measurement as an alternative

Explanatory measurement offers an alternative to this common approach—it provides the same outcomes, the scores or estimates of the construct, but goes well beyond that. The approach was laid out for item response modeling by Rijmen et al. (2003), and expanded on in a volume edited by De Boeck and Wilson (2004) on explanatory item response models (EIRM). Various models

are illustrated with verbal aggression data (Vansteelandt, 2000) using the NLMIXED module from SAS (SAS Institute, 1999). While this software was convenient at the time, the approach can be more readily implemented using newer software, as will be briefly discussed later. The explanatory approach is inspired by generalized linear (and nonlinear) mixed models (McCulloch and Searle, 2001) and related multilevel modeling (Goldstein, 2003; Raudenbush and Bryk, 2002), by Robert Sternberg's work on processes underlying intelligence using individual regression models to link item covariates to item responses (response times and accuracy) (Sternberg, 1977), and by Susan Embretson's covariate-approach for cognitive processes (Whitely, 1976, 1977). The approach is also in line with Ben Wright's insistence (Wright and Masters, 1981) on the importance of the interpretation of both item difficulties and person locations using item maps—commonly referred to as Wright maps (Wilson, 2017).

In terms of ability measurement based on binary data, the rationale underlying EIRM is that if one wants to know what makes, say, a cognitive ability item difficult (as reflected in the item difficulty parameter) and what makes an item more sensitive to the ability level (as reflected in the discrimination parameter), one can begin to answer questions such as why an individual's ability level is higher or lower and what is being measured beyond just referring to the specific set of items used in the calibration. For other types of constructs and for polytomous items, the rationale is analogous, with difficulty replaced with one or more thresholds.

All explanation is based on covariation, whether empirical or conceptual as in Wright maps. EIRM focuses on the covariation between properties of items and parameters of the same items, such as their intercept (difficulty, threshold, or thresholds) and slope (discrimination). In principle, the covariation can be tested in a second step after model estimation, but in EIRM the covariation is part of the model, which is why measurement implies explanation. In a similar way, person-level covariates can be included in the model to explain the person parameters (the latent variable values), but those are not discussed here; see Van den Noortgate and Paek (2004) for more information.

Let us start from the conditional logit for binary data assuming a two-parameter formulation:

$$\eta_{pi} = \alpha_i \theta_p - \beta_i \quad (1)$$

where η_{pi} is the conditional logit (conditional on θ_p but omitted in the notation) for respondent p ($p = 1, \dots, P$) and item i ($i = 1, \dots, I$),

θ_p is the latent variable value for respondent p (η_{pi} is conditional on θ_p) with $\theta_p \sim N(0, 1)$, which can be relaxed under certain conditions, for example, with a histogram distribution (Adams et al., 1997).

α_i is the item discrimination of item i , and

β_i is the item difficulty,

so that the conditional probability of a correct response (π_{pi}) can be written as:

$$\pi_{pi} = \frac{\exp(\eta_{pi})}{1 + \exp(\eta_{pi})} \quad (2)$$

In an EIRM focussing on explanation in terms of item difficulties, the item difficulty is modeled as:

$$\beta_i = \sum_{k=0}^K \beta'_k X_{ik} + \varepsilon_{\beta i} \quad (3)$$

with $X_{i0} = 1$ for all values of i , and β'_0 as the intercept, and where.

k is an index for item properties, $k = 0, 1, \dots, K$,

X_{ik} is the value of item i on item covariate k , and

$\varepsilon_{\beta i}$ is the residual term for the difficulty, $\varepsilon_{\beta i} \sim N(0, \sigma_{\beta}^2)$.

Without the residual term, the model is a fixed-effects model and implicitly assumes that the item difficulties can be fully explained by the item covariates (De Boeck, 2008; Janssen et al., 2004). But this is a strong assumption, seldom realized in empirical applications (see Wilson and Carstensen (2007) for one such example), hence the model with a residual term is more realistic. This leads to a crossed-random effects model because both respondents and the items are random.

In an EIRM, the item discrimination or the log of the item discrimination can also be modeled as a function of item properties. Eq. (4) is written without the log of the discrimination parameter:

$$\alpha_i = \sum_{k=0}^K \alpha'_k X_{ik} + \varepsilon_{\alpha i} \quad (4)$$

with the β notation replaced with an α notation. A similar distinction is made for the discrimination as for the difficulty between a fixed effects model and a random effects model. The model with fixed effects on the discrimination was first described by Embretson (1999). One complication, however, is that the item response model with a discrimination parameter can also be formulated as $\eta_{pi} = \alpha_i(\theta_p - \beta_i)$, which implies a different interpretation, not of α_i , but of β_i , with possible consequences for the explanation of the difficulty parameter in terms of item covariates (Smits et al., 2003). Using Eq. (1), $\exp(-\beta_i)/[1 + \exp(-\beta_i)]$ is the probability of a 1-observation if $\theta_p = 0$ or if $\alpha_i = 0$. No such interpretation is possible for the $\alpha_i(\theta_p - \beta_i)$ parameterization, and when $\alpha_i = 0$, the probability of a 1-observation is 0.50, which does not always make sense.

Examples

An example of modeling item difficulties

As an example of modeling the item difficulty, we briefly summarize the model and results for a one-dimensional mental addition test for first-grade students (Janssen et al., 1999). The data used for the model are speeded responses (with a time limit of 4 s) to 10 addition tasks with integers (from 1 to 4) and a maximum sum of 5: $1 + 1$, $2 + 1$, $1 + 2$, $2 + 2$, $3 + 1$, $1 + 3$, $4 + 1$, $1 + 4$, $3 + 2$, $2 + 3$ presented to (a) a normal ability group and (b) a disability group. The model chosen by the authors did not employ a discrimination parameter and the difficulty was modeled as a linear function of four item covariates based on the following item features:

- (1) whether one of the numbers is a 1,
- (2) whether the two numbers to be added are equal (a tie problem),
- (3) when the second number is larger than the first, the size of the second number, and
- (4) a covariate specific for the $1 + 2$ addition, because one can simply count 1, 2, 3 to find the correct response (i.e., it is very familiar to students).

An additional complexity of the model is an item-related group difference parameter to estimate a hypothesized effect that the five easiest items are easier for the normal ability group than for the disability group. This group difference parameter, specific to a subset of the items, is called a saltus parameter (Wilson, 1989). The model also contains an overall group effect. All four item covariates were found to have statistically significant effects. The effects of item covariates 1, 2, and 4 make the items easier, and the effect of item covariate 3 makes items more difficult. Together the covariates predict almost all of the differences between item difficulties. The correlation between the item difficulty estimates from the Rasch model (with a saltus parameter) and the predicted difficulties is 0.995, indicating that the model is doing a good job of encompassing the Rasch model item difficulty estimates; the likelihood ratio test comparing the explanatory model with the Rasch model (both with a saltus parameter) was not significant. Because the explanation of the item difficulties was nearly perfect, no residual term was needed.

An example of modeling item loadings

As a second example, we briefly summarize the model and results for a two-dimensional depression and anxiety questionnaire with 15 items (Xu et al., 2018). Here the model is not an item response model but a linear factor model with two factors, which illustrates that explanatory measurement can be generalized to multidimensional models. The item loadings (functioning as item discrimination parameters in factor analysis) are modeled as a linear function (not using the log as in Eq. 4) of two item covariates: distress and arousal (the relevance of each of these two aspects of affect, as rated for each of the 15 items). A random item residual term is added to accommodate for an imperfect explanation of the loadings. The item covariates were not used to explain the item intercepts because the item covariates do not contain level information but relevance information instead.

It was found that the loadings on one factor depend on the distress property of the items and the loadings on the other factor depend on the arousal property of the items. The model fit is comparable with a correlated confirmatory two-factor model with depression and anxiety as factors and better than a bifactor model with a general factor and group factors for depression and anxiety. The approach shows that measurement can be brought closer to theory than with confirmatory factor models (CFA). In a CFA, the confirmatory aspect refers to the exclusive association of groups of items with only one factor. The loadings on other factors are constrained to zero, so that there is only one item group per factor. With item covariates that directly refer to important affective features of depression and anxiety as specified in the core affect theory (Russell, 2003) the confirmatory model is at the same time more fine-grained and more flexible (because of the residual term), while preserving the measured constructs.

While the possible uses of such explanations of item parameters will vary due to the context of the application, two examples can be readily generalized to other situations as follows. For a classroom teacher knowing that some features tend to make items easier, she might start the class with examples that have these features (initially singly, but also in combination where that makes sense), and then move onto other examples with features that make the problem more difficult. For a test developer, the features related to item discrimination and item difficulty can be used to generate a new set of items intended to measure the same construct as with the original set, a parallel form, for example, for a pretest/posttest situation.

Random respondent coefficients in the explanative models (random slopes)

Explanatory measurement models, as presented in Eq. (3) and in principle also as presented in Eq. (4), can be extended with random respondent coefficients (i.e., random in p) reflecting the random effects of item covariates. This formulation is referred to as “random slopes” in the multilevel modeling literature; we will refer to it this way in what follows. This means that the β'_k differ depending on the respondent, which can be denoted with an extra subscript p : β'_{pk} . For example, for the mental addition case referred to above (Example 1), the effect of the size of the second number if it is larger than the first could be considered as a source of individual differences rather than as a uniform effect. To explain the corresponding cognitive process, we use a metaphor of weightlifting. To solve the mental addition task (such as $1 + 4$, where the second number is greater than the first) in an efficient

way, the second and larger number is “lifted” to be in front of the smaller first number (i.e., $1 + 4$ is transformed into $4 + 1$). The assumption is that the larger the “weight” to be lifted, the more power one needs to succeed (e.g., $1 + 4$ is more difficult than $1 + 3$, because a 4 is larger (“heavier”) than a 3). This random slope extension of an explanatory measurement model is a way to capture meaningful specific respondent abilities that can help to identify strengths and weaknesses in subcomponents of tasks.

Dimensions based on the coefficients of explanative models (i.e., “slopes-based”) are latent variables and have some interesting features:

- (1) Similar to cognitive diagnostic models (Rupp et al., 2010), they can fulfill a diagnostic role without the limitations of (i) the mixture modeling required for cognitive diagnostic models and (ii) the binary conceptualization of mastery inherent in those models.
- (2) The item covariate values fulfill the role of fixed discriminations for items on the latent variables.
- (3) The latent variables are effects of item covariates as independent variables. In item response models and in factor models the latent variables are commonly conceptualized as independent variables in a regression model with the item responses as the dependent variables, such that the discriminations (i.e., the loadings) are seen as the effects on the item responses. This conceptualization can be problematic because the latent variables are in fact derived from the item responses. Slope-based latent variables can solve this problem; in this new conceptualization, the independent variables are the item covariates while the latent variables are seen as their *effects* on the item responses, with the added flexibility that these effects can differ across respondents. In this way, the independent variables are no longer hypothesized variables. Instead, they are item covariates.
- (4) An interpretation of slope-based latent variables is more objective in that the interpretation does not depend just on a conceptual link in the mind of the test developer or item writer nor a link between a construct and a set of items. Instead, the item covariates themselves are seen as defining the latent variable. This can be empirically grounded and tested.

Differences between the common approach and the explanatory approach

Compared with the common measurement approach, EIRM can be characterized as follows.

Sets of items as indicators

Explanatory measurement shares the usual operationalization of a construct through a set of items, but it also goes beyond the set of items in that item covariates are specified. The additional requirement leads to a better elaboration of the construct. If one cannot specify for an ability construct the kind of difficulty that needs to be overcome, then the construct is not fully specified and the validity of the measure must be called into question.

This kind of difficulty is an item covariate, a property of the items. If the difficulties vary across items (which they almost always do), the hypothesis that this item property makes items more difficult can be tested. This requires that items be designed based on hypothesized difficulty covariates. The result is that the test can be thought as a repeated measurements “experiment” with a covariate for the repeated measures.

The effects of item covariates can be dimensions

Explanatory measurement offers the opportunity to go beyond the average of a respondent’s responses and incorporates a more sophisticated model-based indication of a construct than just the average response or respondent estimate in that the effect of item covariates on the item responses can also be measured. For example, for mental addition, some students may have more issues than others when the second number is larger.

This random slope implies a separate dimension, different from the one defined by a sum score or respondent estimate. Covariates with a random effect across persons define dimensions of the task that can be measured as random slopes.

Measure and explain at the same time

The validity question is formulated in a partially different way for explanatory measurement. Traditionally, a distinction is made between internal validity and external validity, with the former referring to the relationships between variables within a test (items, factors) and relationships with external variables, respectively. For example, internal consistency concerns the relationship between items, item fit indicates that an item fits with the latent variable as assumed by the model, and a finding that a confirmatory factor model for a scale fits well provides evidence for how the scale is conceptualized. In all or almost cases, these indications refer to relationships across respondents, of which correlations are the prototypical examples. As an example of external validity, convergent and discriminant validity is based on high correlations with alternate measurements of the same construct and low correlations with measures of different constructs. Similarly, SEM models can also be used to investigate external validity.

Our discussion of the role that explanatory measurement can play in validation is based on Embretson’s concepts of construct representation and nomothetic span (Whitely, 1983). Explanatory measurement adds something important to the investigation of

internal and external validity based on a different kind of relationship, one between item responses and item covariates. It provides evidence for internal validity in the sense that we can now specify the specific item properties that make an item more difficult and we can investigate whether the expected relationship (this time across items) is empirically supported. This is the construct representation aspect of internal validity in Embretson's terms. When there also are individual differences in the expected relationship, these can be related to external variables. This is the nomothetic span aspect of external validity in Embretson's terms. Thus construct representation and nomothetic span can be simultaneously investigated with an explanatory measurement approach.

An additional, interesting potential use of explanatory measurement is the investigation of possibly confounding aspects of items. If an item covariate that should not affect the item difficulty does in fact make items more difficult—especially when the effect is different depending on the respondent—this is a source of invalidity, and the items should be adjusted accordingly. See De Boeck et al. (2016) for an example.

Descriptive and explanatory

The common approach to the investigation of validity in measurement is to first measure and then explain. Often, the reason to measure is an explanatory research question. Once a construct is measured, one can think of testing a hypothesis in which the construct has an explanatory role, or another variable has an explanatory role vis-a-vis the construct. Explanatory measurement brings an explanatory component into the measurement itself, without an additional external step.

Generality of explanatory measurement

Although explanatory measurement has been discussed primarily for the Rasch family of models, without discrimination parameters (De Boeck and Wilson, 2004; De Boeck et al., 2011), the explanatory measurement idea can be implemented for any parameters of a measurement model, whether it is an item response model (IRT) or a factor model. In theory, any modeled parameter can be made a function of item covariates and person covariates: difficulties and intercepts, discriminations (slopes) and loadings, guessing parameters, person parameters (the latent variables), mixture probabilities, etc. The covariates can be item covariates, person covariates, and covariates of person-by-item pairs. As an example of the latter, De Boeck et al. (2016) have modeled word spelling responses with an item covariate that indicates whether the respondent knows the word in question or not, which is specific to person-by-item pairs. It also is possible to use response category covariates, such as the extremity of response categories on a Likert scale, whether the response category is a midpoint category, and the social desirability of the response category, etc. For multiple-choice response options covariates can also be considered. This then leads to response tree models (e.g., Böckenholt, 2012; De Boeck and Partchev, 2012; Jeon and De Boeck, 2016). Item tree models have not yet been framed as explanatory models in that way in the literature, but it is possible for sequential or continuation ratio models (e.g., Tutz, 1990) as well as for divide-by-total models (Masters, 1982).

Although, in principle, models can be extended to include explanatory components for their parameters, the model extensions can add too much complexity such that the practical feasibility is an important consideration. The most straightforward extensions are those with item covariates for difficulty parameters and person covariates for the latent variable, as noted above.

The explanatory function for a parameter either does or does not include a residual term. In practice it is rare that a full explanation or nearly full explanation can be obtained for a real data set. The earlier example for mental addition tasks is an exception where the explanation is nearly perfect, as is the situation described in the Wilson and Carstensen (2007) paper. A discussion of the issue is provided in De Boeck et al. (2016). The inclusion of a random residual tends to increase the standard error of covariate effects, so that a test of their effects is more stringent. Another consequence of introducing a residual term is that the model contains a random item effect (i.e., the residual item term) (De Boeck, 2008). As a result, the common maximum likelihood estimation methods are no longer feasible, and one needs to rely on approximate methods such as alternating imputation posterior estimation (Cho and Rabe-Hesketh, 2011), variational approaches (Rijmen and Jeon, 2013), or Bayesian estimation methods (Janssen et al., 2004).

Looking beyond data analysis: the construct map

The discussion about EIRM above may convey the impression that the main place in measurement where explanation is important is during the analysis of the data from the respondents interacting with items. But, indeed, the explanative expressions in Eqs. (3) and (4) above are useful only when the possibility of explanative features has previously been built into the thinking and planning about the item design. There are several critical steps in the cycle of measurement instrument development where this design strategy can be employed: (a) during the development of the underlying construct, (b) during the development of the item design, (c) during the coding and scoring of the responses from the respondents, and as extensively explained in the previous sections of this chapter, (d) during the analysis of the resulting data (These form the four building blocks of the BEAR Assessment System—Wilson, 2005). The impact of taking this explanative design strategy will take on a mainly qualitative rather than quantitative nature during the first three of these steps; hence, these design activities will generally not be expressed using equations as in (3) and (4) above, but nevertheless will take on a particular nature due to the aims of the strategy.

Although other foci may be possible, here we will focus on the expression of the explanatory strategy via the difficulty of the items involved, bearing in mind that, due to the nature of the modeling we are using, this will also inherently involve the ability of the respondents. To this end, a somewhat generalized strategy has been introduced, called a Construct Map, which embodies a developmental perspective on the latent variable in question. From this perspective the aim of the measurement is conceptualized not simply as a matter of quantitatively expressing an amount of knowledge, skills or attitude. Focussing on the measurement of knowledge or skills, one can see the underlying cognitive process being the addition of progressively higher levels of competence as new knowledge/skills are linked to existing knowledge/skills and as deeper understandings are developed from and take the place of earlier understandings. The underlying variable here needs to be derived in part from research into the hypothesized cognitive structure of the domain and in part from professional knowledge about what constitutes higher and lower levels of performance or competence but is also informed by empirical research into how respondents respond to training/instruction or perform in practice (NRC, 2001).

Consider the example of a construct map illustrated in Table 1. This Functions construct map is based on an important topic within the mathematics curriculum—making connections across multiple representations of mathematical functions (e.g., National Council of Teachers of Mathematics, 2000). The Functions construct map is based on the SOLO taxonomy (Biggs and Collis, 1982; Biggs, 1999), a general assessment-development framework that is used to assess student ability to make connections within and across topic areas. This general approach was readily applied to the area of mathematical functions, as the aim was to assess student ability to do just that for the topic of multiple representations of mathematical functions—see the successively complex levels represented by the rows in Table 1. The standard SOLO format of levels displays five levels of students' increasingly complex understanding. Here, this is modified by adding a lower and initial level called "Prealgebraic." Above that, going from bottom to top, the qualitatively differentiable levels represent increasing sophistication of *both* student understanding of the connections among mathematical functions *and* of relative difficulty of items designed to generate responses at these levels. For more information about the levels and to see examples of common student responses, see Wilmot et al. (2011, pp. 265–6).

Even though the distinctions among qualitatively different levels of sophistication is seen as crucial to this approach, so too is the expectation that, as a student is making progress toward those higher levels, their progress in between those levels can be discerned as being consistent with a continuous conception of development. Thus, although one might be able to design two items that are

Table 1 The functions construct map.

<i>Functions learning progression: Making connections across multiple representations of mathematical functions</i>		
<i>Levels of sophistication</i>	<i>Student is able to:</i>	<i>Response to items</i>
Extended Abstract (EA)	Make connections not only within a given subject area, but also beyond it, able to generalize and transfer the principles and ideas underlying the specific instance.	• Predict, explain and synthesize their understanding to a real-world context. • Solve non-routine problems including non-algorithmic functions.
Relational (R)	Demonstrate understanding of the significance of the parts in relation to the whole.	• Compare/contrast information given in multiple representations of functions to demonstrate understanding of the content. • Recognize which representations to choose for the context. • Select representations and move fluently among them to achieve a solution.
Multistructural (MS)	Make a number of connections, but the meta-connections between them are missed, as is their significance for the whole.	• Make connections across more than two representations (e.g., tabular, symbolic, graphic and verbal representations) • Recognize more than one feature of a functional relationship.
Unistructural (US)	Make simple and obvious connections, but their significance is not grasped.	• Make pairwise connections between representations.
Prestructural (PS)	Acquire bits of unconnected information, which have no organization and make no sense.	• Interpret graphs where both variables have to be interpreted, or where time is independent variable. • Demonstrate understanding of function in one representation.
Prealgebraic (PA)	Acquire prerequisite skills	Demonstrate understanding of: • Functional dependence, where a change in one variable affects another variable. • Continuous variables (time, distance) and dichotomous variables (hot or cold) • Relative order and measurement to define variables

Note: Read from bottom to top.

distinctively aimed at assessing two qualitatively different consecutive levels in a construct map, one can also design items that will fall at many points in between those distinct levels. Equivalently, two specific students may well generate responses that are typical of two consecutive levels, but other students can be found whose responses reflect many intervening positions. To embody this expectation of latent structure, and because the relationship of the item difficulty parameters to respondent ability is particularly straightforward for the Rasch-type models, the family of Rasch models is typically used to calibrate the items designed to match a construct map (e.g., see Wilson, 2005).

Apart from being a design principle used to create new items, and to code and score the responses from those items, a construct map can also serve as a principal way to interpret the respondent and item parameters that are the output from a test calibration. An example of how these are displayed in an item map (aka Wright map) is shown in Fig. 1. The first column of this Figure (from the far left) shows empirical locations for levels on the construct map—these are the combined levels of the Construct Map that were eventually found to be empirically supported (using an interpretative procedure known as “construct mapping” (Draney and Wilson, 2011)) as being distinguishable after the data have been calibrated and the results appraised. The second column indicates the estimated ability of the students, and difficulties for item thresholds, in logit units. The third column on this map shows the distribution of the students (as an “on-its-side histogram”) who took the Functions items in an administration of the test, and where each “X” in the histogram corresponds to 4 students. Then there are 8 more columns, one for each of the 8 items (named at the top of the 8 columns). The calibrated difficulty of the thresholds between the levels of each of the tasks is indicated by the entry within each of those columns. The Wright map allows one to estimate the probability of a student (or group of students) for each of the items, and, by extension, for the set (or “band”) of students in each of the construct map levels.

Considering now the interpretations of the resulting empirical construct levels, one can see for example, that the combined top construct map levels, EA and R, include only a few students and that for these they would be likely to give a Relational response to several of the tasks, for example, the “24 h crude oil” and the “100-years Crude Oil” tasks (Note: these item thresholds are denoted by “R” in the columns on the right hand side of the Figure). Below that, one can see that most of the students are located within the combined MS and US band, while the lowest levels, comprising the combined PS and PA band, are represented by fewer students.

This map then, allows for an explanation of student results on this set of items by showing how different locations on the map can be interpreted as relating to the likelihood of certain types of student response indicating levels of student understanding about mathematical functions. The outcomes are not so clear as one would wish however, as the detail in the hypothesized construct map has not been fully realized, but rather a grainier interpretation has been attained, distinguishing only 3 consecutive levels of interpretation. This can be ascribed in this case to (a) inconsistent difficulties of location of the MS and US thresholds in the middle bands of the construct map (which may be due to the distinction between these being not so important in this case as is assumed in the SOLO structure), and (b) fewer students being found at the two extremes (that is, the calibration sample might be more

informative if students were sampled from a wider grade level range). Note that this example has been chosen to reflect both strengths and weaknesses of the approach. Other examples of this approach may be found in [Duckor et al. \(2017\)](#), [Schwartz et al. \(2017\)](#), and [Wilson and Lehrer \(2021\)](#).

Research issues

There are several important research issues that deserve more attention to further develop explanatory measurement. Some of these issues are discussed here: (1) extensions to other parameters than item difficulty and to factor models, (2) goodness of fit measures, (3) diagnostic potential and relationships with cognitive diagnostic modeling, (4) test design.

1. Explanatory measurement has been widely used, primarily with item response models (IRT) and for modeling the difficulty parameter and the latent variable. For extensions to two-parameter models, a choice needs to be made between two formulations: $\alpha_i(\theta_p - \beta_i)$, and $\alpha_i\theta_p - \beta_i$, with consequences for the meaning of the β_i parameter and possibly for the precision of the β_i estimate as well. A greater challenge exists with respect to multidimensional models when items are associated with more than one dimension, in the so-called “within-dimension” models ([Adams et al., 1997](#)), or when none of the discriminations or loadings (i.e., in a factor model) are fixed to zero and the discriminations (or loadings) are modeled as a linear function of item covariates. This is especially a challenge when a residual term is used, as in the model of [Xu et al. \(2018\)](#). For this promising development to be more broadly used, an intense study of model identification is needed. Such a development may allow us to overcome the too heavy restrictions of confirmatory models which impose discrimination and loading values to be zero. While on the one hand, explanatory models of this type would be more flexible than confirmatory models, on the other hand, they would be more theory-based and confirmatory because all loadings are considered at least tentatively subject to linear effects of the item covariates.
2. Goodness of fit is an important issue for all models. It is rather straightforward to evaluate relative goodness of fit with AIC and BIC for maximum likelihood estimation, and with DIC and some more recently developed indices such as the WAIC and LOO-CV for Bayesian methods ([Vehtari et al., 2017](#)). If the models are nested, likelihood ratio methods can also be used for maximum likelihood results. It is less straightforward to evaluate absolute goodness of fit. One may consider bootstrap procedures and data recovery methods based on residuals combined with out of sample prediction, but it would also be helpful to develop limited information goodness of fit indices, such as RMSEA, as have been developed for item response models (e.g., [Maydeu-Olivarez, 2011](#)).
3. The random slopes of explanatory measurement models have the potential to capture components of item responses so that more differentiated information can be extracted from the item responses, which would be useful for diagnostic purposes. Thus far, explanatory measurement models have been used primarily for research purposes and for the evaluation of internal validity. With this formulation, we believe that explanatory measurement can fulfill the same role that cognitive diagnostic models aspire to. It would help if research and practice-based comparisons would be made between the two approaches. The comparison can be facilitated with the Q-matrix, which is, in essence, an item covariate matrix and thus can be used directly in explanatory measurement, although in a different way than in cognitive diagnostic models.
4. Related to the previous point and similarly for the cognitive diagnostic modeling approach, it will be beneficial to develop tests based on a test design. Test design has also been promoted by [Embretson \(1985, 1998\)](#), and also by authors associated with Principled Assessment Design PAD ([Wilson and Tan](#), this volume) based on the same ideas that underlay explanatory measurement and the use of covariates. For example, in Embretson’s writings and research, the focus is on cognitive processes underlying item responses, which is a highly valuable approach. Process oriented evidence is an important basis for the validation of tests, as also stressed in the Standards for Psychological and Educational Testing ([AERA/APA/NCME, 2014](#)). Moving to design-based test development would make explanatory measurement a more standard and feasible approach, but it also implies challenges and a need for further research and development, including regarding the practicality of test design and whether it can be combined with criteria such as content validity and representativeness of a domain.

Software

For the estimations of EIRMs, general purpose software is available as well as more specific IRT software. The following are general purpose software tools: The SAS NLMIXED procedure ([SAS Institute, 1999](#)) is used for all chapters of [De Boeck and Wilson, 2004](#)). The R package lme4 ([Bates et al., 2015](#)) can be used for models without a discrimination parameter, and is illustrated by [De Boeck et al. \(2011\)](#). Gllamm ([Rabe-Hesketh and Skrondal, 2016](#)) can also be considered, for example, see <http://www.gllamm.org/aggression.html>.

The following are more specific IRT software programs: Conquest ([Adams et al., 2020](#)) can estimate item covariate models for threshold parameters, as well as person covariates, using design matrices. EIRM ([Bulut, 2021](#)) estimates item covariate models for binary and polytomous item responses. FLIRT ([Jeon and Rijmen, 2016](#)) estimates item covariate models for both the difficulty and the discrimination parameters. Mirt ([Chalmers, 2012, 2015](#)) estimates item covariate models for item difficulty and discrimination with random item residuals, using a Metropolis-Hastings Robbins-Monro algorithm for model estimation, which is an advantage

for high dimensionality. TAM (Robitzsch et al., 2021) estimates item covariate models for item difficulty and item slopes. Finally, brms (Bürkner, 2017, 2021) is more general than IRT: It is a general Bayesian multilevel program and is the most general software package thus far for explanatory item response models.

Diagnostic classification models (DCMs; Rupp et al., 2010) are classification-based psychometric models that efficiently group examinees by their levels of competency for the latent variables of interest. The DCM framework assumes that the latent variables, referred to as *attributes*, have categorical rather than continuous distributions. The discrete nature of the latent variables utilized in DCMs distinguishes them from other psychometric models such as those in the Item Response Theory (IRT) family of models. IRT models utilize continuous latent variables to characterize and estimate latent traits. The choice of whether to assume that the distribution of a latent construct is continuous or categorical depends on the assessment purpose and developers' and users' intended interpretations of the assessment results. An IRT model produces continuous scores along one or more latent continua allowing for rank ordering and comparing examinees' estimated positions on a given continuum. A DCM, on the other hand, produces statistically-driven groupings of examinees according to attribute states allowing for classifying examinees by sets of characteristics.

Diagnostic assessments—assessments that yield classifications of attributes via a DCM—are designed to provide more fine-grained detail about examinee characteristics with reasonable test lengths. Reliable classifications require shorter assessments than reliable continuous scales do; thus, utilizing DCMs in coordination with a careful diagnostic assessment design process enables a multidimensional assessment to remain reasonable in length. The intended use of diagnostic assessment results may be to better understand the multifaceted nature of a construct or to better inform next steps for tailoring an intervention or treatment. In education, a student's diagnostic result may be used to tailor instructional supports for areas identified as weaknesses, providing a more personalized and efficient path to learning.

To support intended diagnostic interpretations of examinee classifications, diagnostic assessments require an evidence-based assessment design process. This process begins with determining the measurement domain, or defining the construct of interest, and then includes developing assessment items to adequately represent the domain. Then, the DCM can be specified to model these attributes and item-attribute relationships, as well as estimate examinee classifications. DCM specifications include choices for modeling how attributes are related to each other, as well as how attributes behave to produce an item response. Once sample data is collected to calibrate the DCM, results provide empirical evidence to evaluate hypotheses of the specified attributes. Results may be used to adjust model specifications or may provide sufficient evidence to support the interpretations of the examinee classifications as meaningful groups according to the attribute states.

In this entry, we briefly discuss the process of specifying attributes and writing items to specify item-attribute relationships, and then we focus on specifying the DCM.

Determining the measurement domain

One of the first steps in constructing a diagnostic assessment requires developers to determine the construct(s) that they want to measure. Then, prior to item development, knowledge domain or content experts operationalize or define a set of attributes as the target construct(s). To accomplish this task, experts must identify a set of attributes that span the essential competencies that

an examinee typically needs in the target knowledge domain (e.g., Bradshaw et al., 2014). This set of attributes is the set of latent traits measured in the diagnostic assessment. For each examinee-attribute combination, the DCM will provide a diagnosis.

The diagnoses or groupings that result from DCMs are typically assigned labels that have meaning and guide decision making. The labels for the groupings depend on the nature of the attributes and the intended interpretation(s) of the classifications. Attributes can represent specific abilities, misconceptions, knowledge components, affective characteristics (e.g., motivation, attitudes, values), skills, or other characteristics that are defined *a priori* by content experts and, ideally, supported by cognitive theories (Leighton and Gierl, 2007). Although polytomous attributes (attributes with more than two levels) that each follow a categorical distribution may be utilized within a DCM framework (Bao, 2019), this entry assumes that attributes are binary and that each attribute follows a Bernoulli distribution. Binary attributes typically have contrasting labels such as “mastery” versus “non-mastery.” Alternate labels include (a) “present” versus “absent,” (b) “proficient” versus “emerging proficiency,” (c) “on-track” versus “needs attention,” (d) “competent” versus “needs improvement,” or (e) attribute *possession* versus no attribute possession (Bradshaw and Levy, 2019). This entry uses the labels “competency” and “non-competency” to depict the two attribute levels, or the two examinee groups for each attribute.

Classifications such as competent or non-competent refer to the examinee’s status on individual attributes. When considering the set of all attributes measured by the diagnostic assessment, the pattern of competencies across the set of attributes describes the examinee’s overall group classification. This collection of attribute-level classifications is referred to as an *attribute profile*, *attribute pattern*, or *latent class*.

To make these concepts more concrete, consider a diagnostic assessment that measures four attributes. This hypothetical assessment and its items will be used for illustration throughout this entry. The DCM will determine whether each examinee is competent or non-competent for each attribute. Then, each examinee will have four attribute-level classifications. For example, suppose the DCM determines that Examinee J is competent on Attribute 1, competent on Attribute 2, non-competent on Attribute 3, and competent on Attribute 4. Examinee J’s set of attribute-level classifications (competent, competent, non-competent, competent) represents a specific attribute profile.

More generally, when using only binary attributes, the total number of all possible unique attribute profiles is 2^A where A is the number of attributes measured by a diagnostic assessment. A DCM-based latent class, α_c , can be represented by an A -length vector: $\alpha_c = [\alpha_{c1}, \alpha_{c2}, \dots, \alpha_{cA}]$, where $c \in \{1, 2, \dots, 2^A\}$ refers to the class number and $a \in \{1, 2, \dots, A\}$ refers to the attribute number. Each term α_{ca} is binary and has a value of 1 when class c is competent for attribute a and 0 when class c is non-competent for attribute a . For the example diagnostic assessment that measures four attributes, $A = 4$ and the DCM will assign each examinee to one of the 2^4 (i.e., 16) possible attribute profiles. These 16 profiles are represented by $\alpha_1 = [0000]$, $\alpha_2 = [0001]$, $\alpha_3 = [0010]$, $\alpha_4 = [0011]$, $\alpha_5 = [0100]$, $\alpha_6 = [0101]$, $\alpha_7 = [0110]$, $\alpha_8 = [0111]$, $\alpha_9 = [1000]$, $\alpha_{10} = [1001]$, $\alpha_{11} = [1010]$, $\alpha_{12} = [1011]$, $\alpha_{13} = [1100]$, $\alpha_{14} = [1101]$, $\alpha_{15} = [1110]$, and $\alpha_{16} = [1111]$. Therefore, Examinee J has the attribute profile $\alpha_{14} = [1101]$ because $\alpha_{14,1} = 1$, $\alpha_{14,2} = 1$, $\alpha_{14,3} = 0$, and $\alpha_{14,4} = 1$.

Because the number and nature of the attributes is determined *a priori*, the latent classes are hypothesized and specified prior to item development, item administration, and data analysis. Thus, DCMs are confirmatory latent class models because after fitting a DCM to collected response data, the results will provide evidence that supports or refutes the hypothesized specification of attribute profiles. Additionally, content experts can update or refine the theories from which the attributes were drawn to accommodate the empirical evidence obtained from DCM analyses (e.g., Bradshaw et al., 2014, 2017–2021; Jacobson et al., 2016). The cycle of creating theories, using theories to create assessments, and using assessment results to advance and improve theories results in stronger knowledge bases on which to build stronger assessments.

Specifying and confirming the latent dimensionality structure for multidimensional assessments is a complex endeavor. Initial empirical evidence may be utilized to refine attribute hypotheses. Updated hypotheses then may be evaluated using subsequent samples. Informing DCM specifications with empirical evidence in this way may be repeated until strong evidence for the model specifications is amassed through the iterative process.

Determining the measurement model and developing items

After specifying the target attributes and attribute profiles, developers and content experts create items to measure the attributes. Substantial knowledge of content and the target examinee population is required to write items that successfully elicit the intended attributes.

Item development highlights another way in which DCMs are confirmatory models: Like the attributes and latent classes, the item-attribute relationships are hypothesized and specified *a priori*, and the subsequent DCM-based data analysis provides evidence that supports or refutes the hypothesized item-attribute relationships. These hypothesized relationships are typically displayed in an array called the *Q-matrix* (Tatsuoka, 1983). The rows of the Q-matrix represent the n items included in the assessment, and the columns represent the A attributes measured by the assessment. Thus, the Q-matrix has the dimensions $n \times A$. If item i is hypothesized to measure attribute a , then the corresponding entry (i, a) in the Q-matrix has a value of 1. If item i is not hypothesized to measure attribute a , then the corresponding entry (i, a) in the Q-matrix has a value of 0. A q -vector for an item is the row of the Q-matrix that corresponds to the item. More specifically, q -vectors are A -length vectors of 0s and 1s, with each entry indicating whether the item measures the corresponding attribute.

The accuracy of the hypothesized item-attribute relationships is important as Q-matrix misspecification decreases the estimation accuracy of the model which prevents valid interpretation of assessment results (e.g., [Rupp and Templin, 2008](#)). Evidence to evaluate the hypothesized item-attribute relationships may be collected via content expert review and/or examinee interviews prior to specifying and estimating the DCM to strengthen the accuracy of the Q-matrix and, as a result, the accuracy of the DCM classifications.

The general latent class model

Classical Test Theory (CTT) is a sum score-based approach to psychological measurement that hinges on the theory that, for a given latent construct, each examinee has a true score with respect to a given construct. However, the construct is latent, so we cannot directly measure the true score in the same way that we can use a ruler to measure the length of a table. Therefore, we must rely on observed scores from assessments to estimate examinees' true scores, and we must accept that such an approach includes unavoidable uncertainty or error and do our best to minimize measurement error.

The goal with CTT is to estimate an examinee's true score. The goal with DCMs is to estimate, or diagnose, an examinee's level of competency with respect to each measured attribute. In other words, the goal with DCMs is to estimate an examinee's true latent class. Like a true score, we cannot directly observe an examinee's true latent class, so we rely on their scored item responses and use the responses to estimate the examinee's true latent class. This estimate, from a measurement perspective, is the class to which the examinee *most likely* belongs. DCMs compute the probability that an examinee belongs to each latent class, given the examinee's responses and the model's estimated parameters which include estimates of how prevalent the attribute profiles are and how items are related to attributes in the population. These probabilities are known as *posterior probabilities*. The examinee's most likely class is the class whose posterior probability is greatest. Based on each examinee's most likely class, one can compute the proportion of examinees who are in each latent class. Using the class proportions, one can compute the attribute *base rates*—the marginal proportion of examinees who are competent for each measured attribute.

DCMs determine posterior probabilities using the general latent class model, which is parameterized as

$$P(\mathbf{X}_e = \mathbf{x}_e) = \sum_{c=1}^{2^A} v_c \prod_{i=1}^n \pi_{ic}^{x_{ie}} (1 - \pi_{ic})^{1-x_{ie}} \quad (1)$$

In the equation, $\mathbf{x}_e$ is examinee e 's *item response vector*—the n -length vector that includes the observed, scored item responses for examinee e where $e \in \{1, 2, \dots, N\}$ and N is the total number of examinees in a sample. [Eq. \(1\)](#) computes the probability ($P(\cdot)$) of observing $\mathbf{x}_e$ given that the examinee belongs to latent class c . The probability that an examinee belongs to latent class c is denoted by the structural parameter v_c . The probability that an examinee in class c provides a correct response to item i is denoted by the measurement parameter π_{ic} . Examinee e 's response to item i is denoted as x_{ie} . This entry focuses on dichotomous (e.g., correct versus incorrect for cognitive domains; endorsement versus non-endorsement for affective domains) rather than polytomous (e.g., partial credit; nominal) item responses. Therefore, $x_{ie} = 1$ if examinee e 's response to item i is correct, and $x_{ie} = 0$ if examinee e 's response to item i is incorrect.

The general latent class model includes then two components: the *structural component* of the model with structural parameter estimates that describe the latent attribute distributions and relationships, or correlations, among the latent attributes, and the *measurement component* of the model with measurement parameter estimates that describe the item-attribute relationships. Each of these components requires its own model specification.

Specifying the structural model

The structural model in the DCM framework is analogous to models in the Structural Equation Modeling (SEM; e.g., [Kline, 2011](#)) framework where relationships among latent variables are modeled.

The structural parameter v_c represents the weight of latent class c among the other classes. Because each examinee is assigned to exactly one latent class, the latent classes are mutually exclusive. As a result, the class proportions sum to one ($v_1 + \dots + v_c + \dots + v_{2^A} = 1$).

[Rupp et al. \(2010\)](#) describe multiple ways to specify the structural model for a DCM. Options include using a log-linear model which parameterizes the latent attributes and their interactions for predicting the probability of latent classes, higher-order models which parameterize the latent attributes for predicting latent class membership through higher-order continuous variables, or an unstructured or a structured tetrachoric model.

Specifying the measurement model

The measurement model in the DCM framework links the observed response data and the unobserved latent attributes. A number of different options for a DCM measurement model have been developed. The choice of which model to use depends on the nature of the attributes and items and the desired interpretations of the diagnostic assessment results. The next section will describe some of the most commonly used DCM measurement models as well as extensions of these models that can be used in more complex contexts.

The measurement model parameterizes the *item response probability* (IRP) conditional upon class, represented by π_{ic} in [Eq. \(1\)](#). The IRP is the probability of answering an item correctly. Examinees with the same attribute profiles share the same IRPs; however,

depending on the number of attributes that an item measures, examinees who do not have identical attribute profiles may also have the same IRPs, as long as their profile is equivalent with respect to the measured attributes.

Consider again the example diagnostic assessment that measures four attributes. Suppose that Item 1 measures all four attributes. The A -length q -vector for Item 1 is [1111]. For a general DCM, because Item 1 measures all attributes included in the assessment, it has $2^4 = 16$ unique IRPs. Now suppose that Item 2 has the q -vector [0101]. Item 2 has only four unique IRPs because it only measures Attributes 2 and 4. Therefore, all attribute profiles that have the same competency states for Attributes 2 and 4 will have the same IRP for Item 2. In other words, it does not matter whether the attribute profile shows 0 or 1 for Attributes 1 and 3 because the item only measures Attributes 2 and 4. Table 1 demonstrates the conditional IRPs for Item 2. Notice that some attribute profiles are partially equivalent because they have the same competency states for Attributes 2 and 4 and, therefore, have the same IRPs for Item 2 regardless of their competency states for Attributes 1 and 3.

For non-general DCMs, an item's attribute behavior may be constrained to form other equivalence classes for the IRPs based on the constraint assumptions. For example, the chosen DCM for the example assessment might set a rule for Item 2 indicating that only examinees who are competent for both attributes measured by the item are likely to answer correctly while examinees who are competent for only one or neither of the two measured attributes have the same chance of answering correctly, and they are unlikely to answer correctly. Such a rule would reduce to a total of two IRPs for Item 2. With different model constraints applied to the item, different types of measurement models for DCMs are defined.

Local independence of items is a key assumption in item response models. In the DCM framework, local independence assumes that item responses are independent given the latent class. This assumption ultimately requires that the attribute(s) measured by an item completely explain the variation in examinee responses. In other words, local independence assumes that the Q -matrix captures all latent traits within the construct domain that influence an examinee's ability to respond to the item. The product part of Eq. (1) is only meaningful under the local independence assumption because of the multiplicative rule for independent events: the probability that independent Events X and Y (e.g., Event X is the selection of a correct response for Item 1 and Event Y is the selection of an incorrect response for Item 2) both occur is the product of their individual probabilities, $P(X) \cdot P(Y)$. As a result, correct specification of the Q -matrix becomes vitally important because the Q -matrix determines how class-specific probabilities are exhibited in the model. If the Q -matrix is misspecified, some variance in examinees' item responses is left unexplained, resulting in a violation of the local independence assumption (e.g., Rupp and Templin, 2008).

DCM measurement model parameterization

Different DCMs have been developed to have different approaches for modeling the item-attribute relationships and most have been shown to be nested within several general DCMs, contingent on model reparameterization. These flexible, general models can specify a wide variety of DCMs (de la Torre, 2011; Henson et al., 2009; von Davier, 2005). This entry focuses on one such model: the log-linear cognitive diagnosis model (LCDM; Henson et al., 2009). The first subsection shows the saturated form of the LCDM

Table 1 Conditional item response probabilities and corresponding attribute profiles for Item 2 with the q -vector [0101].

Item response probability	Abbreviated attribute profile	Attribute profiles included
1	[*0*0]	$c_1 = [0000]$ $c_3 = [0010]$ $c_9 = [1000]$ $c_{11} = [1010]$
2	[*0*1]	$c_2 = [0001]$ $c_4 = [0011]$ $c_{10} = [1001]$ $c_{12} = [1011]$
3	[*1*0]	$c_5 = [0100]$ $c_7 = [0110]$ $c_{13} = [1100]$ $c_{15} = [1110]$
4	[*1*1]	$c_6 = [0101]$ $c_8 = [0111]$ $c_{14} = [1101]$ $c_{16} = [1111]$

Note. The asterisk indicates that it does not matter whether the attribute profile shows 0 or 1 for Attributes 1 and 3 because the item only measures Attributes 2 and 4.

which can fully investigate how examinee responses are connected to latent attributes and their interactions. The second subsection demonstrates how the LCDM reparametrizes some previously-developed DCMs that, in isolation and with their original parameterizations, may appear unrelated.

The log-linear cognitive diagnosis model

In educational and psychological assessment, the LCDM models the log-odds of a correct response to item i for an examinee with the attribute profile for class c , α_c . Eq. (2) shows that a log-linear model expressed in its logit form is equivalent to the linear predictor $\lambda_{i,0} + \lambda_i^T h(\alpha_c, q_i)$.

$$\log\left(\frac{\pi_{ic}}{1 - \pi_{ic}}\right) = \log\left(\frac{P(x_{ie} = 1 | \alpha_c)}{P(x_{ie} = 0 | \alpha_c)}\right) = \lambda_{i,0} + \lambda_i^T h(\alpha_c, q_i) \quad (2)$$

Applying the exponential function to both sides of Eq. (2) and solving for the IRP, π_{ic} , yields the logistic regression form of Eq. (2):

$$\pi_{ic} = P(x_{ie} = 1 | \alpha_c) = \frac{\exp(\lambda_{i,0} + \lambda_i^T h(\alpha_c, q_i))}{1 + \exp(\lambda_{i,0} + \lambda_i^T h(\alpha_c, q_i))} \quad (3)$$

The linear predictor, called a *kernel*, is a combination of linear regression effects including intercepts, attributes' main effects, and higher-order attribute interaction effects. The kernel is written in vector notation to show its most general form. The vector λ_i^T contains all attribute main effects and higher order attribute interaction effects, which are similar to those in analysis of variance models where predictors are also categorical. These effects are item parameters estimated through the LCDM. Each effect has a set of corresponding attributes. For example, each main effect corresponds to one attribute, and each two-way interaction effect corresponds to two of the measured attributes.

The A -dimensional attribute profile for an examinee in class c is denoted as $\alpha_c = [\alpha_{c1}, \alpha_{c2}, \dots, \alpha_{ca}, \dots, \alpha_{cA}]$. The A -dimensional q -vector for item i is denoted as $q_i = [q_{i1}, q_{i2}, \dots, q_{ia}, \dots, q_{iA}]$. The function $h(\alpha_c, q_i)$ reduces to a vector of the same length as λ_i^T that consists of 0s and 1s which are determined by whether item i measures the corresponding attributes (via q_i) and whether an examinee in class c is competent for the corresponding attributes (via α_c). The product of vector λ_i^T and vector $h(\alpha_c, q_i)$ results in a sum of the main and interaction effects, where the effects are retained in the equation only if item i measures all of the corresponding attributes and if examinees in class c are competent for all of the corresponding attributes. Eq. (4) gives the expanded form of the kernel.

$$\lambda_{i,0} + \lambda_i^T h(\alpha_c, q_i) = \lambda_{i,0} + \sum_{a=1}^A \lambda_{i,1(a)} (\alpha_{ca} q_{ia}) + \sum_{a=1}^{A-1} \sum_{a' > 1}^A \lambda_{i,2(a,a')} (\alpha_{ca} \alpha_{ca'} q_{ia} q_{ia'}) + \dots \quad (4)$$

As mentioned above, the kernel contains three types of parameters: an intercept, main effects, and interaction effects. The first term in Eq. (4) is the intercept parameter, $\lambda_{i,0}$, which gives the log-odds that an examinee who is not competent for any attribute measured by item i will provide a correct response to item i .

The second term in Eq. (4) includes the sum of the products of the main effect parameters, $\lambda_{i,1(a)}$, and their corresponding α_{ca} and q_{ia} statuses. Each main effect parameter indicates the increase in the log-odds of a correct response that comes with achieving competency for attribute a conditioned on being non-competent for the other measured attribute(s). Main effect parameters are reflective of an item's discrimination, or the item's ability to discriminate between different competency statuses for attribute a . Additionally, main effect parameters must be positive to adhere to the monotonicity constraint that examinees who are competent for attribute a have a greater IRP than do examinees who are non-competent for attribute a .

The third term in Eq. (4) includes the double summation of the products of the two-way interaction parameters, $\lambda_{i,2(a,a')}$, and their corresponding α_{ca} , $\alpha_{ca'}$, q_{ia} , and $q_{ia'}$ statuses. Each two-way interaction effect parameter indicates the change in the log-odds of a correct response that comes with achieving competency for both attributes a and a' . Notice that for the two-way (and higher-order) interaction effect parameters we cannot say that the change is an increase as it is for the main effect parameters because this is not always the case. Interaction effects may be positive, negative, or zero depending on how the attributes interact and impact examinees' IRPs. However, like main effect parameters, interaction parameters employ constraints that support the assumption that acquiring additional competencies with respect to the measured attributes cannot decrease an examinee's IRP.

The ellipses in Eq. (4) represent the three-way and other higher-order (up to A -way) interactions that can be incorporated into the model if appropriate.

The subscripts of linear lambda coefficients follow particular naming rules. The first subscript represents the item number. The second subscript represents the level of effect where "0" represents the intercept, "1" represents the main effects, "2" represents the two-way interaction effects, and so on. The third subscript indicates the attribute(s) that contribute to the effect. For example, $\lambda_{i,1,(a)}$ is the main effect of attribute a for item i and $\lambda_{i,2,(a,a')}$ is the two-way interaction of attributes a and a' for item i .

Consider the example diagnostic assessment that measures four attributes. The kernels for the items in this assessment could have up to four main effects, six two-way interaction effects, four three-way interaction effects, and one four-way interaction effect, as shown in Eq. (5):

$$\begin{aligned}
\text{kernel}_i = & \lambda_{i,0} + \lambda_{i,1,(1)}\alpha_{c1}q_{i1} + \lambda_{i,1,(2)}\alpha_{c2}q_{i2} + \lambda_{i,1,(3)}\alpha_{c3}q_{i3} + \lambda_{i,1,(4)}\alpha_{c4}q_{i4} + \lambda_{i,2,(1,2)}\alpha_{c1}\alpha_{c2}q_{i1}q_{i2} \\
& + \lambda_{i,2,(1,3)}\alpha_{c1}\alpha_{c3}q_{i1}q_{i3} + \lambda_{i,2,(1,4)}\alpha_{c1}\alpha_{c4}q_{i1}q_{i4} + \lambda_{i,2,(2,3)}\alpha_{c2}\alpha_{c3}q_{i2}q_{i3} + \lambda_{i,2,(2,4)}\alpha_{c2}\alpha_{c4}q_{i2}q_{i4} \\
& + \lambda_{i,2,(3,4)}\alpha_{c3}\alpha_{c4}q_{i3}q_{i4} + \lambda_{i,3,(1,2,3)}\alpha_{c1}\alpha_{c2}\alpha_{c3}q_{i1}q_{i2}q_{i3} + \lambda_{i,3,(1,2,4)}\alpha_{c1}\alpha_{c2}\alpha_{c4}q_{i1}q_{i2}q_{i4} + \lambda_{i,3,(1,3,4)}\alpha_{c1}\alpha_{c3}\alpha_{c4}q_{i1}q_{i3}q_{i4} \\
& + \lambda_{i,3,(2,3,4)}\alpha_{c2}\alpha_{c3}\alpha_{c4}q_{i2}q_{i3}q_{i4} + \lambda_{i,4,(1,2,3,4)}\alpha_{c1}\alpha_{c2}\alpha_{c3}\alpha_{c4}q_{i1}q_{i2}q_{i3}q_{i4}
\end{aligned} \tag{5}$$

Recall example Items 1 and 2 with the respective q -vectors [1111] and [0101]. Because Item 1 measures all of the attributes included in the assessment, $q_{11} = 1$, $q_{12} = 1$, $q_{13} = 1$, and $q_{14} = 1$. The Item 1 kernel retains all possible lambda parameters, yielding an equation identical to Eq. (5) where all of the q 's equal one. Because Item 2 measures only Attributes 2 and 4, $q_{21} = 0$, $q_{22} = 1$, $q_{23} = 0$, and $q_{24} = 1$. Therefore, every term in Eq. (5) that contains q_{i1} or q_{i3} equals zero. Eq. (6) gives the LCDM kernel for Item 2.

$$\text{kernel}_2 = \lambda_{2,0} + \lambda_{2,1,(2)}\alpha_{c2} + \lambda_{2,1,(4)}\alpha_{c4} + \lambda_{2,2,(2,4)}\alpha_{c2}\alpha_{c4} \tag{6}$$

As discussed above, Item 2 has four distinct IRPs. The first IRP is for examinees who are non-competent for Attributes 2 and 4 ($\alpha_{c2} = 0$ and $\alpha_{c4} = 0$), denoted as [*0*0]. The kernel used to compute the first IRP equals $\lambda_{2,0}$. The second IRP is for examinees who are non-competent for Attribute 2 but competent for Attribute 4 ($\alpha_{c2} = 0$ and $\alpha_{c4} = 1$), denoted as [*0*1]. The kernel used to compute the second IRP equals $\lambda_{2,0} + \lambda_{2,1,(4)}$. The third IRP is for examinees who are competent for Attribute 2 but non-competent for Attribute 4 ($\alpha_{c2} = 1$ and $\alpha_{c4} = 0$), denoted as [*1*0]. The kernel used to compute the third IRP equals $\lambda_{2,0} + \lambda_{2,1,(2)}$. Finally, the fourth IRP is for examinees who are competent for Attributes 2 and 4 ($\alpha_{c2} = 1$ and $\alpha_{c4} = 1$), denoted as [*1*1]. The kernel used to compute the fourth IRP equals $\lambda_{2,0} + \lambda_{2,1,(2)} + \lambda_{2,1,(4)} + \lambda_{2,2,(2,4)}$.

Suppose we fix $\lambda_{2,0} = -1.5$, $\lambda_{2,1,(2)} = 1$, $\lambda_{2,1,(4)} = 4$, and $\lambda_{2,2,(2,4)} = 1$ for Item 2. Table 2 shows the kernels and IRPs for the four different types of attribute profiles. As we can see, examinees who are non-competent for Attributes 2 and 4 have the lowest IRP while examinees who are competent for both Attributes 2 and 4 have the greatest IRP. The large main effect for Attribute 4 results in an increase in the IRP for examinees who have achieved competency for only Attribute 4 that is greater than the increase in the IRP for examinees who have achieved competency for only Attribute 2.

Constraining the LCDM to yield common DCMs

As described above, the LCDM is a general DCM that can yield other common DCMs when various parameters in the saturated LCDM are constrained. To demonstrate how the LCDM can be constrained differently for different items, this entry provides parameterization for three sub-models of the LCDM. These three models and others can be categorized into two groups: non-compensatory models and compensatory models. The critical difference between the two models is the characteristic, or the assumption, of attribute behavior. The attribute behavior assumption directs how the attribute competency contributes to the IRPs (i.e., π_{ic}).

Noncompensatory models

Noncompensatory models assume that non-competency in one attribute cannot be compensated for by competency in another attribute. Thus, the lack of one measured attribute is statistically equivalent to a lack of all measured attribute(s). Three well-known noncompensatory DCMs include the deterministic inputs, noisy "and" gate (DINA; e.g., Junker and Sijtsma, 2001) model, the noisy-inputs, deterministic "and" gate (NIDA; e.g., Junker and Sijtsma, 2001) model, and the noncompensatory reparametrized unified model (NC-RUM; e.g., Hartz, 2002).

The DINA model has exactly two IRPs and assumes monotonicity: the IRP for examinees who are competent on all measured attributes (*completely competent examinees*) is greater than the IRP for examinees who are not competent on all measured attributes (*non-competent examinees*). Therefore, achieving competency on all measured attributes in a noncompensatory model is the only way for an examinee to increase their IRP. To illustrate an item that follows DINA rules, consider the math problem: $\frac{1}{2} \left(\frac{3}{4} + \frac{7}{8} \right)$, which

Table 2 Kernels and item response probabilities for Item 2.

α_c	LCDM kernel	π_{ic}
[*0*0]	$\lambda_{2,0} = -1.5 = -1.5$	$\frac{\exp(-1.5)}{1 + \exp(-1.5)} = .18$
[*0*1]	$\lambda_{2,0} + \lambda_{2,1,(4)} = -1.5 + 4 = 2.5$	$\frac{\exp(2.5)}{1 + \exp(2.5)} = .92$
[*1*0]	$\lambda_{2,0} + \lambda_{2,1,(2)} = -1.5 + 1 = -0.5$	$\frac{\exp(-0.5)}{1 + \exp(-0.5)} = .38$
[*1*1]	$\lambda_{2,0} + \lambda_{2,1,(4)} + \lambda_{2,1,(2)} + \lambda_{2,2,(2,4)} = -1.5 + 1 + 4 + 1 = 4.5$	$\frac{\exp(4.5)}{1 + \exp(4.5)} = .99$

measures two attributes: fraction addition and fraction multiplication. If an examinee is competent on fraction addition but not fraction multiplication, their addition competency will not be enough for them to answer correctly. Likewise, if an examinee is competent on fraction multiplication but not on fraction addition, their multiplication competency will not compensate for addition non-competency, and the examinee is unlikely to answer correctly. A correct response to this item requires dual competency on fraction addition and fraction multiplication.

For the DINA model, only completely competent examinees are expected to answer an item correctly. To adhere to the noncompensatory nature of the DINA model, one can obtain the DINA model by constraining the LCDM main and lower-order interaction effect parameters to be zero, resulting in a kernel with only two parameters: the intercept and the highest order interaction effect parameter. Eqs. (7.1) and (7.2) give the LCDM parameterizations of the DINA model for example Items 1 and 2, respectively.

$$\text{kernel}_{1,\text{DINA}} = \lambda_{1,0} + \lambda_{1,4,(1,2,3,4)}\alpha_{c1}\alpha_{c2}\alpha_{c3}\alpha_{c4} \quad (7.1)$$

$$\text{kernel}_{2,\text{DINA}} = \lambda_{2,0} + \lambda_{2,2,(2,4)}\alpha_{c2}\alpha_{c4} \quad (7.2)$$

In the DINA framework, each item has exactly two kernels, which correspond to the two IRPs. The first kernel for Item 2, $\lambda_{2,0}$, is used to compute the IRPs for examinees with any of the 12 attribute profiles that do not have the partial competency $[*1*1]$. The second kernel for Item 2, $\lambda_{2,0} + \lambda_{2,2,(2,4)}$, is used to compute the IRPs for examinees with any of the four attribute profiles that have the partial competency $[*1*1]$. For Item 1, the second kernel, $\lambda_{1,0} + \lambda_{1,4,(1,2,3,4)}$, is used to compute the IRPs only for examinees with the attribute profile $[1111]$. The first kernel for Item 1, $\lambda_{1,0}$, is used to compute the IRPs for examinees with any of the other 15 attribute profiles.

Compensatory models

Unlike noncompensatory models, compensatory models assume that non-competency in one attribute can be compensated by competency in another attribute. Examinees lacking one attribute can still have a high IRP if they are competent for other attributes.

For example, an extreme case of a compensatory DCM, the deterministic inputs, noisy “or” gate (DINO; Templin and Henson, 2006) model, assumes that competency for one of the measured attributes is statistically equivalent to competency for multiple or all attributes. The DINO model is therefore also referred to as a fully *disjunctive* model, the “opposite” of DINA, a fully *conjunctive* model. The DINO model has exactly two IRPs and assumes monotonicity: the IRP for examinees who are competent for at least one measured attribute (*competent examinees*) is greater than the IRP for examinees who are not competent for any measured attributes (*completely non-competent examinees*). Therefore, examinees can increase their log odds of a correct response by achieving competency for any number of the measured attributes.

The LCDM parameterization of the DINO model imposes two constraints for each item: (1) an item’s main effect and interaction effect parameters are constrained to all have the same value, referred to as a *common main effect* and denoted as $\lambda_{i,1}$, and (2) the main effect parameters are constrained to be positive, the two-way interaction parameters are constrained to be negative, the three-way interaction parameters are constrained to be positive, and so on, alternating positive and negative signs for each parameter level. Eqs. (8.1) and (8.2) give the LCDM parameterizations of the DINO model for example Items 1 and 2, respectively.

$$\begin{aligned} \text{kernel}_{1,\text{DINO}} &= \lambda_{1,0} + \lambda_{1,1}\alpha_{c1} + \lambda_{1,1}\alpha_{c2} + \lambda_{1,1}\alpha_{c3} + \lambda_{1,1}\alpha_{c4} - \lambda_{1,2}\alpha_{c1}\alpha_{c2} - \lambda_{1,2}\alpha_{c1}\alpha_{c3} - \lambda_{1,2}\alpha_{c1}\alpha_{c4} - \lambda_{1,2}\alpha_{c2}\alpha_{c3} - \lambda_{1,2}\alpha_{c2}\alpha_{c4} \\ &\quad - \lambda_{1,2}\alpha_{c3}\alpha_{c4} + \lambda_{1,3}\alpha_{c1}\alpha_{c2}\alpha_{c3} + \lambda_{1,3}\alpha_{c1}\alpha_{c2}\alpha_{c4} + \lambda_{1,3}\alpha_{c1}\alpha_{c3}\alpha_{c4} + \lambda_{1,3}\alpha_{c2}\alpha_{c3}\alpha_{c4} - \lambda_{1,4}\alpha_{c1}\alpha_{c2}\alpha_{c3}\alpha_{c4} \\ &= \lambda_{1,0} + \lambda_{1,1}(\alpha_{c1} + \alpha_{c2} + \alpha_{c3} + \alpha_{c4} - \alpha_{c1}\alpha_{c2} - \alpha_{c1}\alpha_{c3} - \alpha_{c1}\alpha_{c4} - \alpha_{c2}\alpha_{c3} - \alpha_{c2}\alpha_{c4} - \alpha_{c3}\alpha_{c4} \\ &\quad + \alpha_{c1}\alpha_{c2}\alpha_{c3} + \alpha_{c1}\alpha_{c2}\alpha_{c4} + \alpha_{c1}\alpha_{c3}\alpha_{c4} + \alpha_{c2}\alpha_{c3}\alpha_{c4} - \alpha_{c1}\alpha_{c2}\alpha_{c3}\alpha_{c4}) \end{aligned} \quad (8.1)$$

$$\text{kernel}_{2,\text{DINO}} = \lambda_{2,0} + \lambda_{2,1}\alpha_{c2} + \lambda_{2,1}\alpha_{c4} - \lambda_{2,1}\alpha_{c2}\alpha_{c4} = \lambda_{2,0} + \lambda_{2,1}(\alpha_{c2} + \alpha_{c4} - \alpha_{c2}\alpha_{c4}) \quad (8.2)$$

Notice that these parameterizations can be written in the form $\lambda_{i,0} + \lambda_{i,1}(\cdot)$, where the alternating signs in $(\cdot)$ are designed so that the values for $(\cdot)$ are given by the indicator function in Eq. (9).

$$(\cdot) = \begin{cases} 1 & \text{for competent examinees} \\ 0 & \text{completely non-competent examinees} \end{cases} \quad (9)$$

Another commonly-used compensatory model is the compensatory reparametrized unified model (C-RUM; e.g., Hartz, 2002). In C-RUM items, achieving competency for one or more of the measured attributes would yield a greater IRP than would being competent for no attributes. The C-RUM uses the main effects to represent increases in the IRPs for being competent in additional attributes, but sets all interactions effects to zero. Eqs. (10.1) and (10.2) show the LCDM parameterizations of the C-RUM for example Items 1 and 2, respectively.

$$\text{kernel}_{1,\text{C-RUM}} = \lambda_{1,0} + \lambda_{1,1(1)}\alpha_{c1} + \lambda_{1,1(2)}\alpha_{c2} + \lambda_{1,1(3)}\alpha_{c3} + \lambda_{1,1(4)}\alpha_{c4} \quad (10.1)$$

$$\text{kernel}_{2,\text{C-RUM}} = \lambda_{2,0} + \lambda_{2,1(2)}\alpha_{c2} + \lambda_{2,1(4)}\alpha_{c4} \quad (10.2)$$

To illustrate the item response functions for the submodels, [Tables 3](#) and [4](#) show the specific DINA, DINO, and C-RUM kernels for Items 1 and 2, respectively, for each of the 16 attribute profiles in the example diagnostic assessment that measures four attributes.

Extended DCM measurement models

Thus far, this entry has discussed only dichotomous item responses and binary attributes with competent and non-competent diagnoses—labels that are most commonly associated with achievement testing. This section briefly introduces readers to extensions of the base DCMs that accommodate different types of observed variables and modeling frameworks.

Polytomous DCMs

DCMs have been developed to handle polytomously-scored responses ([Chen and de la Torre, 2018](#)), similar to other psychometric models such as graded or nominal item response models ([Kim et al., 2020](#)). The structural and measurement components of the DCM would need to change to accommodate polytomous responses. The structural model adopts a polychoric instead of a tetrachoric correlation. Depending on the contexts, the response variable in the measurement model may be ordinal or nominal. The distribution of the response variable, the link function connecting the response variable, and the linear predictor (the kernel) are then modeled accordingly.

Hierarchical DCMs

The models discussed thus far assume that attributes are not perfectly correlated. In fact, they assume that attributes are correlated but not so much that they cannot be distinguished from one another. However, DCMs have been developed that can manage complete dependency between attributes which is known as an *attribute hierarchy*. When achieving competency for an attribute completely relies on one's competency status with respect to another attribute, the two attributes are said to be part of an attribute hierarchy ([Templin and Bradshaw, 2014](#)). For example, consider a diagnostic assessment that measures two attributes: (1) addition of single-digit numbers and (2) addition of two-digit numbers. One cannot achieve competency for Attribute 2 without achieving competency for Attribute 1. Therefore, Attribute 2 completely depends on the competency of Attribute 1. Because this example assessment measures two attributes, it has four attribute profiles: [00], [01], [10], and [11]. However, the profile [01] is not possible because an examinee cannot be competent on Attribute 2 without being competent on Attribute 1. This profile can be removed, and the total number of possible profiles would reduce to three: [00], [01], and [11], which would also reduce the number of parameters that need to be estimated in the structural model, as well as have implications for the measurement model.

Longitudinal DCMs

Recent research has developed DCMs for longitudinal settings. The longitudinal scenario refers to evaluating examinees' knowledge components over time throughout an extended lesson or intervention, a semester, a school year, or other time frames. The longitudinal DCM can assess examinee growth in the form of transitions between attribute states, while providing diagnostic feedback about examinee understanding at each time point (e.g., [Madison and Bradshaw, 2018](#); [Wang et al., 2018](#); [Xu and Bradshaw, 2020](#)).

Table 3 DINA, DINO, and C-RUM kernels for Item 1 [1111] in the example diagnostic assessment.

Class	Profile	DINA	DINO	C-RUM
1	[0000]	$\lambda_{1,0}$	$\lambda_{1,0}$	$\lambda_{1,0}$
2	[0001]	$\lambda_{1,0}$	$\lambda_{1,0} + \lambda_{1,1}$	$\lambda_{1,0} + \lambda_{1,1(4)}$
3	[0010]	$\lambda_{1,0}$	$\lambda_{1,0} + \lambda_{1,1}$	$\lambda_{1,0} + \lambda_{1,1(3)}$
4	[0011]	$\lambda_{1,0}$	$\lambda_{1,0} + \lambda_{1,1}$	$\lambda_{1,0} + \lambda_{1,1(3)} + \lambda_{1,1(4)}$
5	[0100]	$\lambda_{1,0}$	$\lambda_{1,0} + \lambda_{1,1}$	$\lambda_{1,0} + \lambda_{1,1(2)}$
6	[0101]	$\lambda_{1,0}$	$\lambda_{1,0} + \lambda_{1,1}$	$\lambda_{1,0} + \lambda_{1,1(2)} + \lambda_{1,1(4)}$
7	[0110]	$\lambda_{1,0}$	$\lambda_{1,0} + \lambda_{1,1}$	$\lambda_{1,0} + \lambda_{1,1(2)} + \lambda_{1,1(3)}$
8	[0111]	$\lambda_{1,0}$	$\lambda_{1,0} + \lambda_{1,1}$	$\lambda_{1,0} + \lambda_{1,1(2)} + \lambda_{1,1(3)} + \lambda_{1,1(4)}$
9	[1000]	$\lambda_{1,0}$	$\lambda_{1,0} + \lambda_{1,1}$	$\lambda_{1,0} + \lambda_{1,1(1)}$
10	[1001]	$\lambda_{1,0}$	$\lambda_{1,0} + \lambda_{1,1}$	$\lambda_{1,0} + \lambda_{1,1(1)} + \lambda_{1,1(4)}$
11	[1010]	$\lambda_{1,0}$	$\lambda_{1,0} + \lambda_{1,1}$	$\lambda_{1,0} + \lambda_{1,1(1)} + \lambda_{1,1(3)}$
12	[1011]	$\lambda_{1,0}$	$\lambda_{1,0} + \lambda_{1,1}$	$\lambda_{1,0} + \lambda_{1,1(1)} + \lambda_{1,1(3)} + \lambda_{1,1(4)}$
13	[1100]	$\lambda_{1,0}$	$\lambda_{1,0} + \lambda_{1,1}$	$\lambda_{1,0} + \lambda_{1,1(1)} + \lambda_{1,1(2)}$
14	[1101]	$\lambda_{1,0}$	$\lambda_{1,0} + \lambda_{1,1}$	$\lambda_{1,0} + \lambda_{1,1(1)} + \lambda_{1,1(2)} + \lambda_{1,1(4)}$
15	[1110]	$\lambda_{1,0}$	$\lambda_{1,0} + \lambda_{1,1}$	$\lambda_{1,0} + \lambda_{1,1(1)} + \lambda_{1,1(2)} + \lambda_{1,1(3)}$
16	[1111]	$\lambda_{1,0} + \lambda_{1,4,(1,2,3,4)}$	$\lambda_{1,0} + \lambda_{1,1}$	$\lambda_{1,0} + \lambda_{1,1(1)} + \lambda_{1,1(2)} + \lambda_{1,1(3)} + \lambda_{1,1(4)}$

Note. Item 1 measures all 4 attributes on the example assessment.

Table 4 DINA, DINO, and C-RUM kernels for Item 2 [0101] in the example diagnostic assessment.

Class	Profile	DINA	DINO	C-RUM
1	[*0*0]	$\lambda_{2,0}$	$\lambda_{2,0}$	$\lambda_{2,0}$
2	[*0*1]	$\lambda_{2,0}$	$\lambda_{2,0} + \lambda_{2,1}$	$\lambda_{2,0} + \lambda_{2,1(4)}$
3	[*1*0]	$\lambda_{2,0}$	$\lambda_{2,0} + \lambda_{2,1}$	$\lambda_{2,0} + \lambda_{2,1(2)}$
4	[*1*1]	$\lambda_{2,0} + \lambda_{2,2,(2,4)}$	$\lambda_{2,0} + \lambda_{2,1}$	$\lambda_{2,0} + \lambda_{2,1(2)} + \lambda_{2,1(4)}$

Note. Item 2 measures Attribute 2 and Attribute 4 on the example assessment.

Longitudinal DCMs provide a framework to model theoretical learning trajectories with empirical evidence. These learning trajectories reflect when attribute competencies are acquired relative to each other and provide a discrete description about how examinees evolve from novice to sophisticated learners. Quantitatively vetting theories around how examinees learn, and possibly forget, can put forth new perspectives to curriculum-based learning trajectory research (e.g., Confrey et al., 2014).

Researchers and practitioners can also utilize longitudinal DCMs to evaluate the added value of instruction or learning materials over time and help investigate the effectiveness of an intervention using a pre-/post-test design.

Measuring misconceptions

Traditional assessments score responses as correct or incorrect without considering the specific selected response options. This approach discards potentially valuable information about examinee reasoning that can be found in their specific incorrect responses. A family of assessments called *concept inventories* (e.g., Hestenes et al., 1992) are specifically designed to include incorrect response options that target known plausible, yet incorrect reasoning in the population (*misconceptions*). DCMs have been developed to model misconceptions as the underlying categorical latent traits (de la Torre, 2009; DiBello et al., 2015; Kuo et al., 2016). Some of these models also estimate ability on an underlying continuum (Bradshaw and Templin, 2014) or diagnose skills (Kuo et al., 2018).

In education, identifying and correcting misconceptions as early as possible is critical because misconception can worsen over time (e.g., Fischbein and Schnarch, 1997) and impede learning of new concepts. Diagnostic concept inventories (Bradshaw, 2011; Bradshaw and Templin, 2014; Schellman, 2021) can help teachers identify which examinees possess misconceptions and use the model-based diagnoses to provide differentiated instruction.

Conclusion

This entry presented details of the DCM framework specifically through the lens of the LCDM—a flexible tool that can model multiple, categorical attributes, making it an important step in the process of compiling evidence to support or refute the validity of the intended assessment-based interpretations. Diagnostic assessments provide criterion-referenced information about examinees' individual strengths and weaknesses, which can be used to tailor remediation or interventions in ways that unidimensional information from scaling- or IRT-based assessments cannot. Assessment developers and users, however, must employ the psychometric framework that best supports the purpose of the assessment and the intended assessment-based interpretations, while aligning with practical constraints.

Introduction

Graphical models

The notion of *graphical models* appeared in the work of Speed (1978), Lauritzen et al. (1984), and Darroch et al. (1980). The group of authors developed a class of models—graphical models (Lauritzen, 1996)—with a general formalism, referred to as the Markov property, that enables explicit factorization (decomposition) of graphical models in terms of conditional independencies. According to Lauritzen (1996), graphical models have a fundamental and universal applicability due to three factors. First, graphs provide an easy way to visualize the scientific content of a given model as well as facilitate communication. Second, as a graph, scientific models are naturally modular, and as such, facilitate the description of complex problems, often as a particular combination of simpler elements. Third, graphs offer a useful data structure for communicating with digital computers.

Models as graphs have a long history. Early examples include Wright's path analysis (1934) and the representation of the total energy of a system (Gibbs, 1902)—gas or solid particles occupying a space as neighbors with interaction. The development of graphical models by Lauritzen and colleagues initially focused on undirected graphical models from contingency table data because of their direct formalism with Markov random fields. Kiiveri and Speed (1982) linked this general formalism to linear causal models that were popular in sociology (see Duncan, 1966; Heise, 1975). In the 1980s, Judea Pearl detailed several properties of graphical models (Pearl and Verma, 1987) and developed an algorithmic approach known as *d-separation* (Pearl, 1988) for determining whether any directed graphical model (without loops or cycles) implies any given conditional independence relation (Glymour, 2004).

This work by Pearl ultimately led to the development Bayesian Networks. Pearl initially referred to Bayesian networks as "belief networks, Bayesian networks, or influence networks, interchangeably, the former two to emphasize the judgmental origin and the probabilistic nature of the quantifiers, the latter to reflect the directionality of the links" (p. 246, Pearl, 1986). Bayesian networks have found use in several domains of research including artificial intelligence, computer science, economics, educational assessment, and causal inference (Almond et al., 2015; Hünemund and Bareinboim, 2019; Pearl, 1995; Quintana, 2020). The Markov property of graphical models has also contributed significantly to the development of computational and estimation techniques on graphs (e.g., see Lauritzen and Jensen, 2001; Cowell, 2005; Rijmen, 2008,2009; Rijmen et al., 2008).

In this chapter, we provide a basic overview of the notion and properties of Bayesian networks. We then discuss belief propagation, message-passing, and the recently developed R package, BayesNetBP, that facilitates belief propagation on Bayesian networks (Yu et al., 2020). BayesNetBP is the "first open source package to facilitate exact probabilistic reasoning in the three most common types of Bayesian networks (BNs) (discrete multinomial, continuous Gaussian and conditional Gaussian Bayesian networks)." (p. 2, Yu et al., 2020). We provide a motivating example using BayesNetBP for probabilistic reasoning in the form of a familiar multinomial Bayesian network known as the discrete item response theory (IRT) model (Almond et al., 2015). Finally, we conclude with comments on important topics in the field of Bayesian networks.

Before preceding to our discussion on Bayesian networks, it is important to note that several alternative types of graphical models are not discussed in this chapter. Graphical models generally fall into one of three domains: directed, undirected, and chain graphical models. Directed graphs include graphical models with directed edges and include the focus of this chapter, Bayesian

networks. Undirected graphs include graphical models with undirected edges and are known also as Markov random fields and include, for example, the Ising model or Boltzmann machine. Lastly, chain graphs include graphical models with both directed and undirected edges and are also known as partially directed acyclic graphs. While not discussed in this chapter, these types of graphical models are increasingly finding use in educational assessment and statistics. For example, the use of undirected graphs in educational assessment, statistics, and psychometrics has seen substantial growth in the past decade (e.g., see discussion on “network psychometrics” in [Cramer et al., 2010](#), [Epskamp et al., 2017](#); [Marsman et al., 2018](#); [Savi et al., 2019](#)).

Bayesian networks

Bayesian networks are a subclass of graphical models known as directed acyclic graphs (DAGs). DAGs are graphical models with only directed edges and no cycles. Acyclic refers to the structure of a directed graph defining a partial topological ordering of the nodes ([Scutari and Denis, 2014](#)). Bayesian networks as DAGs allow a concise decomposition of the probabilistic dependencies between a set of random variables $X = \{X_1, X_2, \dots, X_p\}$ that enables the joint distribution of the variables to be represented in a compact factored form. Let $G = (V, E)$ represent a DAG where each node $v_i \in V$ corresponds to a random variable X_i and E corresponds to the directed edges (also known as arcs) in the graph. If there is a direct edge from v_i to v_j , v_i precedes v_j in the topological ordering, and v_i is called an ancestor of v_j and v_j is called a descendant of v_i . If a path between two nodes is composed of only one arc, v_i is a parent of v_j and v_j is a child of v_i (see [Fig. 1](#)).

Maps

The correspondence between the graphical structure ($\perp_G$) and probabilistic structure ($\perp_P$) in Bayesian networks can be formalized in terms of three different mappings ([Nagarajan et al., 2013](#); [Scutari and Denis, 2014](#)). The mappings help categorize the relationship between a probabilistic model and a graph. A graph G is said to be an independence map (I-map) of the probabilistic structure P of X “if there is a one-to-one correspondence between the random variables in X and the nodes V of G , such that for all disjoint subsets A, B, C ” (p. 14, [Nagarajan et al., 2013](#))

$$A \perp_G B | C \Rightarrow A \perp_P B | C \quad (1)$$

That is, G is an I-map of P if B separates A and C in G implies A is independent of C given B in P . If a graph G is an I-map of the probability structure P , then P is said to be Markov with respect to G (i.e., variables separated in G are conditionally independent given the variables that separate them). A graph is said to be a dependency map (D-map) of P of X if

$$A \perp_G B | C \Leftarrow A \perp_P B | C \quad (2)$$

A D-map indicates that for any edge in a graph there is a dependence relationship between variables in the probability model ([Almond et al., 2015](#)). In contrast, in an I-map, there may be edges in a graph whether there are not actually dependencies. Lastly, a graph is said to be a perfect map of P if it is both an I-map and D-map. That is,

$$A \perp_G B | C \Leftrightarrow A \perp_P B | C \quad (3)$$

and we say that P is isomorphic or faithful to G . [Almond et al. \(2015\)](#) note that perfect maps are rare whereas I-maps and D-maps always exist. For instance, connecting all nodes in a graph (i.e., a complete graph) is a trivial I-map and a disconnected graph (no edges) is a trivial D-map ([Almond et al., 2015](#)). When we care about eliciting distributions it is typical to work with D-maps in the

Fig. 1 An example of parents, children, ancestors, descendants, and neighbors of node X in a directed graph.

form of directed graphs (e.g., see the [Probability factorization](#) section where we factorize a graph according to its structure to represent the joint distribution). However, when constructing message-passing algorithms on Bayesian networks it is common to work with I-maps that transform directed graphs into an undirected representation for probability computation (e.g., an elimination tree or junction tree)—we return to the idea of probability computations on trees in the [Message-passing, belief propagation, and probability updating](#) section.

D-separation

The correspondence between the structure of a DAG G and the conditional independence relationships represented in the graph is formally codified by the directed separation (d-separation) algorithm (Pearl, 1988). The d-separation algorithm (here, d stands for directional) allows a computer to easily study independence properties for subgraphs. As such, the d-separation algorithm is a useful process for predicting the shared dependencies in a graph. A formal definition of d-separation is as follows, if A , B , C are three disjoint subsets of nodes in a DAG G , C is said to d-separate A from B , denoted $A \perp\!\!\!\perp_C B|C$, if along every sequence of edges (i.e., a path) between a node in A and a node in B , there is a node v meeting one of two conditions:

1. v is in C and does not have converging arc where C could be a chain ($A \rightarrow C \rightarrow B$) or fork ($A \leftarrow C \rightarrow B$); note that by being in C the node v is conditioned on, or
2. v has converging edges (i.e., there are two directed edges pointing to v) and none of v or its descendants are in C —known as a collider ($A \rightarrow C \leftarrow B$).

The d-separation criterion enables us to assess, for any pair of nodes, whether the nodes are d-connected—that is, there exists a connecting path between the nodes—or d-separated—there is no such path between a pair of nodes. Pearl et al. (2016) note that “When we say that a pair of nodes are d-separated, we mean that the variables they represent are definitely independent; when we say that a pair of nodes are d-connected, we mean that they are possibly, or likely, dependent” (p. 46). With the d-separation criterion, we can now evaluate complex Bayesian networks and determine whether variables are in the graphical model are independent or dependent, both marginally and conditional on other variables.

For example, in Fig. 1, consider the relationship between $C1$ and Z . Given we do not condition on any information (i.e., we have an empty conditioning set), we know that $C1$ and Z are d-separated and that $C1$ and Z are independent. This is because there is no unblocked path between $C1$ and Z . There is only one path between $C1$ and Z and it is blocked by a collider ($Z \rightarrow C2 \leftarrow X$). Conversely, if we now condition on $C2$, the d-separation criterion implies that $C1$ and Z are now d-connected—this is because $C2$ is in the conditioning set. In this case, since the path between $C1$ and Z contains a fork (X) that is not in the conditioning set, and the only collider $C2$ on the path is conditioned on, the path between $C1$ and Z is not blocked. Conditioning on colliders “unblocks” the path between variables. Note the same would be true if we conditioned on $D2$, because $D2$ is a descendant of a collider on the path between $C1$ and Z .

As we will see in the motivating example below, when we condition on a variable to probabilistically reason about the remaining variables in the graph, the d-separation criterion enables us to predict how new observed information flows (propagates) throughout the graph—the probabilities of the remaining d-connected variables in the graph are updated. Specifically, using a graph of the discrete IRT factor model (Fig. 2), we demonstrate (1) how we can observe evidence about item responses to probabilistically reason (or update our beliefs) about an individual’s ability and (2) how we can observe evidence about an individual’s ability to probabilistically reason (or update our beliefs) about that individual’s likelihood of answering an item correctly.

Probability factorization

The Markov property of Bayesian networks follows directly from the definition of d-separation (Nagarajan et al., 2013). The Markov property of Bayesian networks formalizes the representation of a joint probability distribution of the random variables in X (the global distribution) as a product of conditional probability distributions (the local distributions associated with each variable X_i). The Markov property is an application of the chain rule or total law of probability (Almond et al., 2015; Pearl, 2009). In

Fig. 2 Five-item discrete IRT Bayesian network. Squares are used to represent discrete nodes.

the case of discrete variables, the joint probability distribution can be decomposed or factorized as a product of conditional probabilities

$$P_X(X) = \sum_{i=1}^p P(X_i | pa(X_i)), \quad (4)$$

where $pa(X_i)$ is the set of the parents of X_i . In the case of continuous random variables, the joint density function f_X is given by

$$f_X(X) = \sum_{i=1}^p f_{X_i}(X_i | pa(X_i)), \quad (5)$$

Similar results can be derived for the case whether there are both discrete and continuous variables and thus mixed probability distributions. For further details on the properties of Bayesian networks we recommend (Scutari and Denis, 2014; Pearl et al., 2016).

Message-passing, belief propagation, and probability updating

Graphical models embed probability models with graphical structure. Graphical models, as a union of probability and graph theory, provide a visual and modular representation of probability models that facilitates flexible computation of probabilities. Message-passing algorithms (e.g., belief propagation or junction-tree algorithms) on Bayesian networks are basic examples of embedding probability models with graphical structure to compute probabilities. Given that we know the joint distribution from the graphical structure, in principle, we can always compute the effect of new information (observed evidence) for any variable, or subset of variables, on “our beliefs about the remaining variables (i.e., to propagate the evidence)” (p. 105, Almond et al., 2015).

As a simple example, consider the basic DAG ($X \rightarrow Y$). Let X represent a student’s proficiency in mathematics where X can take two values ($x_1 = \text{proficient}$ and $x_2 = \text{not – proficient}$), and Y represent whether the student provides a correct answer to a specific mathematics problem ($y_1 = \text{yes}$ and $y_2 = \text{no}$). Assuming the student is equally likely to be proficient or not-proficient means $p(\text{proficient}) = p(\text{not – proficient}) = 0.5$. Furthermore, assume that a proficient student’s probability of providing a correct answer is 0.6 and a not-proficient student’s probability is 0.3—that is, $p(y_1 | x_1) = 0.6$ and $p(y_2 | x_1) = 0.4$, and $p(y_1 | x_2) = 0.3$ and $p(y_2 | x_2) = 0.7$. In an educational assessment, we would like to observe a student’s performance on a mathematics problem, evaluate its correctness, and update our belief about the student’s proficiency status.

For instance, say we observe that Lynn correctly answers the mathematics problem (i.e., $Y = y_1 = \text{yes}$). With this simple DAG, we can use Bayes theorem to update our current beliefs regarding Lynn’s proficiency status (i.e., 0.5/0.5). In particular, now that we have the news that $Y = y_1$, our updated beliefs about Lynn’s proficiency status (proficient or not-proficient) are as follows

$$p(x_1 | y_1) = \frac{p(y_1 | x_1)p(x_1)}{p(y_1 | x_1)p(x_1) + p(y_1 | x_2)p(x_2)} = \frac{0.6 \times 0.5}{0.6 \times 0.5 + 0.3 \times 0.5} = 0.67 \quad (6)$$

and

$$p(x_2 | y_1) = 1 - p(x_1 | y_1) = 0.33. \quad (7)$$

Almond et al. (2015) demonstrate how these operations for this simple DAG also work on a simple set of conditional probability tables. We briefly note that these operations involve first starting with a table for the initial joint and marginal probabilities and a table for the observed evidence that $Y = y_1$. These initial tables are combined and normalized by $p(y_1)$ to obtain a conditional probability table for X given that $Y = y_1$ —the resulting table allows us to interpret the probabilities $p(x_1 | y_1)$ and $p(x_2 | y_1)$ (See pp. 107–109 of Almond et al., 2015, for further details on these operations).

With trivial examples like the DAG $X \rightarrow Y$, we can update our beliefs or probabilistically reason by hand using Bayes theorem. However, in more complicated DAGs, computer-assisted message-passing algorithms enable more rapid belief updating. The messages that are passed in these algorithms are updated probabilities based on observed evidence. However, the computations involved with updating probabilities on graphs becomes prohibitive as the number of variables in a Bayesian network increases. Almond et al. (2015) note, “A model with 15 variables with four values each ... means working with a joint probability table with over a trillion entries” (p. 105). Message-passing algorithms attempt to modularly represent the topology of probability models on graph structure such that calculations are more computationally efficient. Mathematical topologies that are amenable for computational efficiency are those with small cliques (or low tree width; Almond et al., 2015). Belief propagation is a message passing algorithm for inference on graphical models such as Bayesian networks. After a Bayesian network is constructed, the belief propagation algorithm may be applied to the network.

Almond et al. (2015) note that most Bayesian network software that implement message-passing algorithms operate in two modes: model construction/editing and model manipulation/inference. In the model construction mode, we (1) specify a node for each variable in the DAG and the names and the states of the variables, (2) draw edges between the nodes to depict the conditional dependence relationships in a model, and (3) supply a conditional probability table for each node in the model, given the parents of the node. If a node has no parents, an unconditional probability table is used. After the model is constructed, in the inference model, the model is compiled—that is our initial beliefs are propagated throughout the network—in several examples in Almond et al. (2015) a model is compiled using the Lauritzen and Jensen (2001) approach with junction trees in the commercial software Netica (Norsys). After the model is compiled, most Bayesian network software packages allow for immediate inspection of

the marginal distributions for all nodes. Furthermore, after evidence is propagated throughout the network (known as compiling), we are now ready to probabilistic reason through evidence absorption (i.e., we can make inquiries about the effect of observing or absorbing new evidence in the Bayesian network).

The BayesNetBP R package (Yu et al., 2020) is no different, and has both a model construction step and an inference or probabilistic reasoning step. BayesNetBP is a recently developed R package for implementing the belief propagation algorithm on Bayesian networks that was previously only available in the commercial software such as Hugin (Hugin Expert A/S, 2017) or Netica (Norsys). Each software performs belief propagation, but they differ in their approach or algorithms for implementing belief propagation. For example, Hugin, Netica, and BayesNetBP are based on Lauritzen and Spiegelhalter (1988), Lauritzen and Jensen (2001), and Cowell (2005), respectively. A key difference between the Lauritzen and Cowell approaches is that “message passing takes place on an elimination tree structure rather than the more compact (and usual) junction tree of cliques” (p. 1517). Yu et al. note that the approach of Cowell is “simpler to implement, and can be generalized to accommodate purely discrete or continuous BNs [Bayesian networks]” (p. 10). We do not provide further details on the differences between elimination trees and junction trees (see, Cowell, 2005). Furthermore, we do not cover important ideas such as cliques, elimination order, moralization, or triangulation (see, Yu et al., 2020). We note that the results provided by BayesNetBP in the motivating example below are roughly identical to Almond et al. (2015), albeit negligible differences are noted due to the fact that the local distributions were computed using simulated data. We encourage the reader to consult the references provided herein with particular focus on Chapters 4–6 in Almond et al. (2015).

A discrete item response theory model

Our motivating example for Bayesian networks uses a classical example of a discrete IRT model from Almond et al. (2015). We simulated data to conform with conditional probability table of the discrete IRT model in Almond et al. (see Table 6.1; Appendix A for code). The conditional probability table for the simulated data in this example is (Table 1):

All variables are treated as categorical. In this example, we have five items scored to yield observable values of right (1) or wrong (0). We also have a discrete measure $\theta = \{-2, -1, 0, 1, 2\}$ that represents a student’s proficiency in the mathematics knowledge and skills that this set of items requires. The items range from easy (item 1) to difficult (item 5) with the $\beta = \{-1.5 - 0.75, 0, 0.75, 1.5\}$.

A teacher may be interested in drawing inferences about the mathematics proficiency of each student based on the observed score patterns from this five item test. Given the assumption of local item independence, that is $X_j \perp\!\!\!\perp X'_j \mid \theta$, we can write the joint probability distribution over both the proficiency variable (θ) and evidence variables (items) as

$$P(X_1, \dots, X_J, \theta) = P(\theta) \sum_{j=1}^J P_j(X_j \mid \theta). \quad (8)$$

The factorization structure of the joint probability distribution is represented by the Bayesian network in Fig. 2. Note that a classic IRT model treats the θ variable as continuous. As such, there would be directed edges from the continuous θ to the discrete items which indicates that the standard IRT model does not fall into the computationally convenient class of conditional Gaussian Bayesian networks (see Lauritzen, 1992, and Lauritzen, 1996, for more details). In Fig. 2, since all the variables are discrete, there are no integrals that need to be solved numerically. Almond et al. (2015) note that this discretization of θ may not be that problematic citing Haberman’s (2005) demonstration of how an ordered latent class model (Bayesian network in Fig. 2) and a unidimensional IRT model both fit multiple data sets equally well.

Bayesian networks and belief propagation allow (1) the visual representation of domain information (in our example θ , or proficiency, influences item response behavior), (2) encoding of domain information in terms of conditional independencies on a joint distribution of variables (here, the model encodes the typical IRT assumption of local independence—that is the item responses are independent conditional on θ), (3) simple specification of the joint distribution (see Eq. 8), and (4) rapid computation and updating of given probabilities of interest after observing evidence—Almond et al. (2015) describes this as the facility to “enter data and

Table 1 Conditional probabilities of a correct response for the five-item IRT model in Almond et al. (2015).

θ	Item 1	Item 2	Item 3	Item 4	Item 5
−2	0.3770	0.2150	0.1100	0.0650	0.0290
−1	0.6230	0.4440	0.2480	0.1445	0.0820
0	0.8050	0.6788	0.5005	0.3195	0.1850
1	0.9255	0.8540	0.7460	0.5670	0.3790
2	0.9660	0.9530	0.8180	0.7820	0.6170

play ‘what-if’ games for various hypotheses” (p. 163). In the next few sections, we demonstrate how to use the BayesNetBP package to answer identical questions formulated in Almond et al. (2015). R code is provided in supplemental material (see Appendix A).

In the motivating example below, we first inspect initial marginal probabilities that represent our “best predictions of how a student who we know nothing about, other than that the student is representative of the population for which the model was built, would do on a quiz” (p. 161, Almond et al., 2015). These initial marginal probabilities are in Fig. 3. These marginal probabilities are calculated from the conditional probabilities of a correct response given θ and the initial marginal distribution for θ using the law of total probability. The marginal probabilities are simply the expected proportion correct on each item in a population for whom the quiz was designed (Almond et al., 2015). The marginal probabilities for the items indicate that Items 1 and 2 are relatively easy items with expected proportion correct greater than 60%. On the other hand, Item 4 and 5 are relatively difficult items with expected proportion correct less than 35%.

An advantage of Bayesian network software, versus doing the calculations by hand, is that we can quickly observe evidence on the graph (i.e., absorb or instantiate evidence on the graph). This is the facility to enter data and play “what-if” games for various hypotheses. The first example we demonstrate this facility on is absorbing evidence from the simple five item mathematics quiz. For instance, suppose that Merve, a student in a class taking this mathematics quiz, answers Item 2 and Item 3 correctly (i.e., Item 2 = Right and Item 3 = Right). Note that we have shaded these items gray in Fig. 4 to indicate that they are now observed. We can absorb this new evidence into the graph using BayesNetBP that immediately performs belief propagation. The result is in Fig. 4. The result produces a posterior distribution for Merve’s θ . In particular, we can see that Merve answering Item 2 and 3 correctly has shifted our beliefs in her θ such that there are now higher probabilities for higher values of θ —for instance, we can see that the probability that Merve’s θ is -2 is nearly zero. Furthermore, we can see that the probability that Merve would answer the remaining items correct has also increased—Merve’s probability of answering Item 1 correctly has shifted to nearly 90%. If instead we had observed that Merve answered Items 3 and 4 correctly, we would expect an even greater shift toward higher values of θ since Items 3 and 4 are more difficult than Items 2 and 3 collectively. Note, in this example, we can immediately see that all the variables in Fig. 2 are d-connected because after observing new evidence, all probabilities in the graph were updated. If there were d-separated variables (nodes) in the graph, the probabilities for those nodes would not be updated.

Likewise, we can evaluate the effect of observing evidence about θ —note in practice θ is typically unobservable but Bayesian networks enable us to specify θ values in order to test out various scenarios. For instance, say we know that there are groups of students in the class for which this quiz was designed that had different θ values (e.g., Group A’s θ values are 2 and Group B’s θ values are 1, etc.). We can use the Bayesian network to answer the question, what is the expected performance on each of the items for a member from Group B? In BayesNetBP, we can set $\theta = 1$ and propagate this information through out the Bayesian network to update our beliefs about the probability of a member from Group B answering a given item correctly. Note that we have shaded θ gray in Fig. 5 to indicate that it is now observed. Fig. 5 reports the results of absorbing $\theta = 1$ in the BayesNetBP package (i.e., the updated item probabilities). We can see that a member from Group B is very likely to answer Items 1–3 correctly (probabilities all greater than 75%). However, while the probability of answering Item 4 correctly has increased from the expected proportion correct in the population this test was designed for, Group B members still only have a roughly 50–50 chance of answering the item correctly. Item 5 (the most difficult item) still has quite a low probability of being answered correctly by members of Group B.

Fig. 3 Initial marginal probabilities and propagating prior evidence throughout the Bayesian network.

Fig. 4 Marginal probabilities after absorbing evidence that item 2 and 3 were correct. The shaded grade node indicates that evidence for the node is absorbed.

Fig. 5 Marginal probabilities after absorbing θ equal to 1. The shaded grade node indicates that evidence for the node is absorbed.

These examples demonstrate how we can perform both deductive and inductive reasoning on Bayesian networks. The example in Fig. 4 is an example of inductive reasoning (Almond et al., 2015). From the observed values of the items, the Bayesian network induces a posterior distribution for the unknown proficiency. Likewise, the example in Fig. 5 is an example of deductive reasoning. From the observed value of the proficiency variable, we can deduce the likely consequences (i.e., probability of answering an item correctly). Furthermore, another possible application that is readily available from the Bayesian network in Fig. 5 is that we can calculate the expected weight of evidence (or information) for a particular unobserved item. In the current example, using a result from IRT theory that states that under the Rasch model an item for which a student has 50–50 chance of getting the item right

provides the most information, we can see how the Bayesian network approach provides a simple approach to adaptive testing or item selection.

Additional topics in Bayesian networks

Evidence-centered design

The Evidence-Centered Design (ECD) project created at the Educational Testing Service (ETS) is an approach to constructing educational assessments in terms of evidentiary arguments (Mislevy et al., 2003). The ECD process involves a series of procedures that focus on questions such as: What can we observe about a test takers performance that will provide evidence that the test taker has the knowledge or ability we wish to make inferences about? How can we structure situations to be able to make these inferences? The ECD process results in a formal design for educational assessment that is known as the conceptual assessment framework (CAF). The CAF uses Bayesian networks to represent what we measure (student proficiency model), how we measure (evidence model), where we measure (task model), how much we measure (assembly model), and customization (presentation and delivery models). As with the examples here, ECD aims to use Bayesian networks to probabilistically reason about accumulating evidence across task performance to characterize the knowledge, skills, and/or abilities of students (Mislevy et al., 2003). For information, the reader is referred to Mislevy et al. (2003).

From Bayesian networks to causal networks

The idea of observing evidence on a Bayesian network is also important to Judea Pearl's work on causal inference (Pearl, 2009). This idea has paved the way for the notion of an intervention or do-calculus in Pearl's work on causal inference. For instance, Pearl, using the notion of intervening and do-calculus (i.e., set a variable to a specific observed value like we did in the example above), provides a way to probabilistically reason about causal inferences based on the structure of a graph (or causal model; Pearl, 1995). In fact, a recent book, embodying utility of interventions on Bayesian networks is entitled "Causal Inference: What If" (Hernán and Robins, 2020) where notions of interventions (and planned interventions) are prominently utilized to make causal inferences—recall Almond's quote above about "what-if" games on Bayesian networks. We simply provide a note here to make a connection between Bayesian networks and causal networks. Further information can be found in Pearl (1995) where a discussion is provided about how we can move from Bayesian networks to causal networks as well as in Pearl (2009).

Structure learning

Structure learning is another important idea worth mentioning that has emerged from the Bayesian network literature. In all of our examples herein, the structure of the Bayesian network (i.e., the direction of the edges between the nodes in the graph) was assumed to be known. Structure learning algorithms alternatively attempt to learn the underlying (causal) structure of a Bayesian network or particular features of a causal graphical model (see, for example, Heinze-Deml et al., 2018). Common causal structure learning algorithms come in the form of: (1) constraint-based algorithms, (2) score-based algorithms, and (3) hybrid-based algorithms (i.e., constraint- and score-based). Further, causal structure learning algorithms have been developed for structural equation models with non-Gaussian noise, for exploring invariance properties, for time series data, for mixed data (i.e., continuous and discrete), and Bayesian methods (see Heinze-Deml et al., 2018 for more details). Causal structure learning algorithms have not found widespread use in education. Notable examples include Fancsali (2014), Quintana (2020), and Rau and Scheines (2012).

Parameter learning

In the example above, we build on a common presentation of Bayesian networks in educational assessment that utilizes message-passing, belief propagation, and probability updating. The example is useful because it demonstrates how we can update our beliefs and probabilistically reason about individual students' proficiency based on information in their responses to items. However, it is important to note that this example assumes that the proficiency and conditional probability distributions for the observed variables are known. In other scenarios where we use Bayesian networks, we may be interested in estimating these distributions or parameters. Note, that the practice of "parameter estimation" in the statistics literature is commonly referred to as "parameter learning" in the literature on Bayesian networks and graphical models (e.g., Koller and Friedman, 2009). The term learning stems from the use of Bayesian networks in the machine learning and artificial intelligence communities.

Parameter learning in Bayesian networks is distinct from structure learning. Parameter learning generally assumes that the structure of the Bayesian network is already known or already learned from the data. Once the structure of the Bayesian network is known, estimating and updating the parameters is often simplified by decomposing the global distribution into a set of local distributions. From these local distributions, two approaches to parameter estimation are common: maximum likelihood estimation (MLE) and Bayesian estimation. For example, Koller and Friedman demonstrate how, using the properties of Bayesian networks, the likelihood function of MLE decomposes as a product of independent terms, one for each of conditional probability distribution in the network. They refer to this as the *global decomposition* of the likelihood function. We do not cover any further details on the maximum likelihood and Bayesian estimation of Bayesian networks in this chapter. However, detailed discussion on both

approaches to parameter estimation or learning, for both binary and continuous nodes, is provided in [Almond et al. \(2015\)](#) and [Koller and Friedman \(2009\)](#).

Summary

In this chapter, we provided a basic overview of the notion and properties of Bayesian networks. We discussed belief propagation, message-passing, and the recently developed R package, BayesNetBP for performing belief propagation on Bayesian networks. We also provided a motivating example using BayesNetBP for probabilistic reasoning in the form of a familiar multinomial Bayesian network known as the discrete IRT model ([Almond et al., 2015](#)). We provided two examples that demonstrate how we can observe evidence to perform inductive and deductive reasoning on a Bayesian network (i.e., either performance on an item or a student's proficiency level).

There are important topics not discussed here including belief propagation on conditional Gaussian Bayesian networks ([Lauritzen, 1996](#)), which is also available in the BayesNetBP package. Conditional Gaussian Bayesian networks facilitate message-passing techniques when there are both continuous and discrete nodes in a Bayesian Network, albeit without directed edges from continuous nodes to discrete nodes. Directed edges from continuous nodes to discrete nodes do not fall into the computationally convenient class of conditional Gaussian Bayesian networks ([Lauritzen, 1992, 1996](#))—that is, all integrals involved in a Bayesian network can be solved in closed form ([Almond et al., 2015](#)). We also do not discuss alternative Bayesian network formulations such as factor graphs or influence diagrams (see [Sucar, 2015](#)) nor extensions to Bayesian networks such as dynamic Bayesian networks (see [Levy, 2019](#)).

In summary, Bayesian networks are a type of graphical model that represents a set of variables and their conditional dependencies in a DAG. Bayesian networks provide a useful tool for visualizing the knowledge about some domain and embedding a probabilistic model for this domain. As the examples in this chapter demonstrate, Bayesian networks are useful for taking knowledge about an event or events that have happened and predicting the likelihood of some variable of interest. That is, Bayesian networks facilitate probabilistic reasoning by allowing us to make inquiries about the state of some variable given some observed evidence. Bayesian networks have been extended to develop educational assessments, make causal inferences, perform parameter and structure learning, and design efficient computational and estimation techniques.

Introduction

Bayesian statistical methods have become popular in the field of psychometrics. Thanks to the development of general purpose Bayesian inference software (e.g., *Stan*; Gelman et al., 2015), researchers are now able to quickly develop and fit sophisticated and complex psychometric models that once required significant computational expertise to estimate. In addition, Bayesian methods also provide a class of approaches alternative to classical or frequentist statistics (e.g., maximum likelihood, confidence intervals, p-values). In certain cases, Bayesian approaches can alleviate some difficulties classical approaches may have. There is abundant literature on applying Bayesian methods to psychometric modeling. Levy (2009) gives a nice overview and survey of the applications of Bayesian estimation for psychometric models. Some specific examples include Bayesian estimation of a broad class of cognitive diagnostic models (Culpepper, 2015; Liu and Johnson, 2019), the extended marginal Rasch model (Maris et al., 2015), a multilevel item response theory (IRT) model (Fox and Glas, 2001), and an unfolding response model (Johnson and Junker, 2003). Other examples include estimating uncertain elements of the Q-matrix in a CDM model (DeCarlo, 2012), nonparametric ordered latent class modeling (Liu, 2019), robust IRT outlier detection (Öztürk and Karabatsos, 2017), and evaluating model fit (Sinharay, 2005, 2015; Sinharay and Almond, 2007). These mentioned examples of Bayesian methods in psychometrics are far from exhaustive. The main purpose of this entry is to give readers a brief introduction to some of the most essential concepts and steps involved in a Bayesian analysis of psychometric models.

Bayesian data analysis

Let X denote the observed random variables (i.e., the data), and θ denote the vector of unobserved random variables (i.e., the parameters). In Bayesian statistics, the parameters are treated as random and are given prior distributions. This is in contrast to the classical likelihood methods where parameters are treated as fixed but unknown. We are typically interested in using the data to estimate and make inferences about the vector of unknown parameters. A Bayesian analysis involves three essential steps:

1. Model specification. In this step, we set up a full probability model that describes the joint probability distribution for all observed and unobserved random variables, i.e., $p(X, \theta)$. According to the definition of conditional probability, this joint probability distribution can be factorized as $p(X, \theta) = p(X|\theta)p(\theta)$. The marginal density, $p(\theta)$, is often referred to as the *prior distribution* which expresses any prior belief we may have on the parameters with uncertainty, and the conditional density, $p(X|\theta)$, is called the *sampling distribution* (or the generating distribution) which describes the data generation process. Setting up these models generally requires some knowledge of the underlying problems with, sometimes, considerations for mathematical convenience.
2. Posterior inference. In this step, we calculate and interpret the *posterior distribution* from which we make inferences about the parameters. The posterior distribution is the conditional distribution of the unobserved random variables (i.e., parameters) which we are typically interested in, given the observed data, i.e., $p(\theta|X) = p(\theta, X)/p(X) = p(X|\theta)p(\theta)/p(X)$. This is known as Bayes' rule. As a function of parameters θ , $p(X|\theta)$ is also referred to as the likelihood function through which the data X influences the posterior distribution of the parameters. To obtain the density of the marginal distribution of the data, we need to evaluate $p(X) = \int p(X|\theta)p(\theta)d\theta$. Except for certain extremely simple models, this (potentially high dimensional) integral cannot be evaluated analytically. Consequently, the posterior is generally not available in closed forms. Instead, the posterior distribution $p(\theta|X)$ is usually approximated using sampling methods such as the Markov chain Monte Carlo (MCMC; Gelman et al., 2013; Neal, 1998).

3. Model fit evaluation. Once a model has been set up and the posterior distribution has been computed, it is important to assess the fit of the model. Inferences drawn from a model that does not fit well could be very misleading. In a Bayesian framework, the assessment of model fit is typically performed through the posterior predictive model checking (PPMC; Gelman et al., 2013; Rubin, 1984). If the model fits reasonably well, the observed data or the derived statistics of our practical interest should look plausible under the posterior predictive distribution. The identified aspects of model misfit could help improve or expand the model. Sometimes, identifying misfit itself could be of practical interest, for example, to identify aberrant response patterns (e.g., Sinharay, 2015).

These steps are true to all Bayesian modeling applications. Bayesian psychometrics is an example of such applications to psychometric modeling. In the following sections, we demonstrate these essential steps of the Bayesian data analysis with a little more details by using a simple 1-parameter normal ogive IRT model as an example.

Model specification

Let $X_{ij} = x_{ij}$ be a dichotomous random variable of the item response from the i^{th} student to the j^{th} item, $i = 1, 2, \dots, N$ and $j = 1, 2, \dots, J$. And $x_{ij} = 1$ if the response is correct, $x_{ij} = 0$ otherwise. Under the 1-parameter normal ogive (1PNO) IRT model, the probability of a correct response is given by

$$P(X_{ij} = 1 | \theta_i, a, b_j) = \Phi(a(\theta_i - b_j)), \quad (1)$$

where $\Phi(\cdot)$ denotes the cumulative probability density function (CDF) of the standard normal distribution, θ_i is the person parameter, b_j is the item difficulty parameter, and a is the common discrimination parameter shared among J items. The person parameter is assumed to follow a standard normal distribution, i.e., $\theta_i \sim N(0, 1)$. Because a is a constant across items, the item characteristic curves (ICC) never cross each other and only differ by locations (see Fig. 1).

The 1PNO as in Eq. (1) can be expressed as a Bayesian hierarchical model. For computational efficiency, we reparameterize the model so that the model is in its slope-intercept form,

$$P(X_{ij} = 1 | \theta_i, \psi_j) = \Phi(\theta_i + \psi_j), \quad (2)$$

and $\theta_i \sim N(0, a^2)$, where a^2 is the variance of the normal distribution.

A prior distribution describes any prior belief we may have (or the lack of it) on the parameter with uncertainty. For instance, in the current example, there may be reasonable prior information on the item parameter ψ_j from similar items previously administered to a comparable population of students. In this case, we may choose a normal prior with mean μ_{ψ_j} informed by prior information and variance $\sigma_{\psi_j}^2$ expressing the level of uncertainty, i.e., $\psi_j \sim N(\mu_{\psi_j}, \sigma_{\psi_j}^2)$. A prior with larger variance (or a flatter prior, see Fig. 2) is less informative and appropriate when there is greater uncertainty about a parameter, thus having less impact on the posterior inference of the parameter. However, prior information may not always be available. In this case, instead of choosing a fixed prior with a large variance, an alternative approach is to use a hierarchical prior. For each item parameter ψ_j , we assign a same Gaussian prior, $\psi_j \sim N(\mu_{\psi}, \sigma_{\psi}^2)$. Hyper-priors are assigned to the parameters of this prior distribution, i.e., $\mu_{\psi} \sim N(0, 10^2)$ and

Fig. 1 ICC of the 1PNO IRT model.

Fig. 2 Density of prior distribution of ψ_j .

$\sigma_\psi^2 \sim Ga^{-1}(10^{-4}, 10^{-4})$, where $Ga^{-1}(\cdot)$ denotes the inverse-gamma distribution (see Gelman et al., 2013, p. 43). The chosen inverse-gamma distribution is noninformative if most of the posterior density is away from 0 as the prior density is flat in the tail. The choice of this set of priors is also mathematically convenient. The normal prior and inverse-gamma prior are conditionally conjugate for the model. A prior is said to be conjugate for the likelihood function if the resulting posterior distribution is in the same probability distribution family. In this case, the conditional posteriors for the mean parameter and the variance parameter normal and inverse-gamma. We choose a similar noninformative inverse-gamma distribution for a^2 , i.e., $a^2 \sim Ga^{-1}(10^{-4}, 10^{-4})$. We can then write the 1PNO IRT model has a Bayesian hierarchical model,

$$\begin{aligned}
 x_{ij}|\theta_i, \psi_j &\sim \text{Bernoulli}\left(\Phi\left(\theta_i + \psi_j\right)\right) \\
 \psi_j|\mu_\psi, \sigma_\psi^2 &\sim N\left(\mu_\psi, \sigma_\psi^2\right) \\
 \mu_\psi &\sim N(0, 10^2) \\
 \sigma_\psi^2 &\sim Ga^{-1}\left(10^{-4}, 10^{-4}\right) \\
 \theta_i|a^2 &\sim N(0, a^2) \\
 a^2 &\sim Ga^{-1}\left(10^{-4}, 10^{-4}\right).
 \end{aligned} \tag{3}$$

Posterior inference

For any practical applications, we are interested in inferring model parameters given the data, in other words, computing the posterior distribution. The *joint* posterior distribution of the parameters, $p(\theta, \psi, \mu_\psi, \sigma_\psi^2, a^2|\mathbf{x})$, cannot be analytically computed. As a result, we use MCMC to sample from this unknown distribution. The simplest MCMC algorithm is perhaps the Gibbs sampling. A Gibbs sampler (Geman and Geman, 1984) works by iteratively sampling from the full conditional distributions of the parameters. Generally, this is feasible if the full conditional distributions can be computed in closed form and sampled from easily. However, this may not be true for some models. In these cases, other MCMC algorithms are required, e.g., the Metropolis-Hastings algorithm (Hastings, 1970). The literature on MCMC algorithms is vast, and the development of new MCMC methods is still an extremely active research area. Readers may refer to Gelman et al. (2013) and Neal (1998) for some detailed introduction and review on this topic.

For our example of the 1PNO model, a direct Gibbs sampling is possible. However, we would need to augment latent variables. For every item response x_{ij} , there is a latent variable y_{ij} associated. The relationship between them is deterministic such that

$$x_{ij} = \begin{cases} 1 & \text{if } y_{ij} > 0, \\ 0 & \text{otherwise,} \end{cases}$$

where $y_{ij} \sim N(\theta_i + \psi_j, 1)$. It is straightforward to verify that, under this specification, the probability of a correct response remains $\int_{-\infty}^{\theta_i + \psi_j} \phi(y) dy = \Phi(\theta_i + \psi_j)$.

To derive the densities full conditional distributions, we use the definition of conditional probabilities and the chain rule. For example,

$$p(y_{ij}|x_{ij}, \theta_i, \psi_j) = \frac{p(x_{ij}|y_{ij})p(y_{ij}|\theta_i, \psi_j)}{\sum_{y_{ij}} p(x_{ij}|y_{ij})p(y_{ij}|\theta_i, \psi_j)}. \quad (4)$$

Notice that the denominator of Eq. (4) is a constant (with respect to y_{ij}) that normalizes the full conditional density. Therefore, we can conveniently write

$$\begin{aligned} p(y_{ij}|x_{ij}, \theta_i, \psi_j) &= Cp(x_{ij}|y_{ij})p(y_{ij}|\theta_i, \psi_j) \\ &\propto p(x_{ij}|y_{ij})p(y_{ij}|\theta_i, \psi_j). \end{aligned}$$

Given that $p(x_{ij}|y_{ij})$ is a piecewise point density with support on either $x_{ij} = 1$ or $x_{ij} = 0$ depending on y_{ij} , the full conditional distribution of y_{ij} is a truncated normal distribution, i.e.,

$$y_{ij}|x_{ij}, \theta_i, \psi_j \sim \begin{cases} N(\theta_i + \psi_j, 1)T(0, \infty) & \text{if } x_{ij} = 1, \\ N(\theta_i + \psi_j, 1)T(\infty, 0) & \text{if } x_{ij} = 0. \end{cases}$$

$T(0, \infty)$ denotes that the distribution is truncated with a lower bound of 0; while $T(\infty, 0)$ denotes a truncation with an upper bound of 0.

The full conditional distributions of other parameters can be derived similarly. Since the priors are chosen so that they are *conditionally* conjugate, the full conditional distributions of the parameters are within the same distribution families as their priors. The standard conjugacy results apply (for a reference, see Gelman et al., 2013). Here, we state the results without detailed derivations.

Now we can summarize the Gibbs sampler. After assigning initial values to parameters, at the M^{th} iteration,

1. for each i and j , update y_{ij} by drawing from $N(\theta_i + \psi_j, 1)T(0, \infty)$ if $x_{ij} = 1$; else draw from $N(\theta_i + \psi_j, 1)T(\infty, 0)$;
2. for each i , update θ_i by drawing from $N\left(\frac{1}{1/a^2 + J} \left(\sum_j (y_{ij} - \psi_j) \right), (1/a^2 + J)^{-1}\right)$;
3. for each j , update ψ_j by drawing from $N\left(\frac{1}{1/\sigma_\psi^2 + N} \left(\mu_\psi / \sigma_\psi^2 + \sum_i (y_{ij} - \theta_i) \right), \frac{1}{1/\sigma_\psi^2 + N}\right)$;
4. update a^2 by drawing from $Ga^{-1}\left(10^{-4} + \frac{N}{2}, 10^{-4} + \frac{\sum_i \theta_i^2}{2}\right)$;
5. update μ_ψ by drawing from $N\left(\frac{1}{1/10^2 + J/\sigma_\psi^2} \left(\frac{\sum_j \psi_j}{\sigma_\psi^2} \right), (1/10^2 + J/\sigma_\psi^2)^{-1}\right)$;
6. update σ_ψ^2 by drawing from $Ga^{-1}\left(10^{-4} + J/2, 10^{-4} + \frac{\sum_i (\psi_i - \mu_\psi)^2}{2}\right)$.

Keep updating long enough, the draws are eventually random samples from the joint posterior distribution. Even though the theory of Markov chains guarantees the eventual convergence to the desired target distribution which is the joint posterior (see Neal, 1998, for a review), in practice, we can only draw finite number of samples. It is important to assess the convergence so that we are reasonably confident using the draws to form valid posterior inference. There are many methods for monitoring the convergence of MCMC (Cowles and Carlin, 1996). For example, the Gelman-Rubin statistic (Gelman and Rubin, 1992) is one of the most popular methods and implemented in many Bayesian computation software.

Once the samples are drawn, to make inferences about parameters, we need to summarize the posterior distribution. Typically, we use mean, mode, and median to describe the central tendencies of the posterior distribution and serve as a point estimate. Among them, posterior mean is probably the most common. In addition to the point estimate, the variance or standard deviation can be used to describe the dispersion of the posterior distribution. We may also be interested in forming posterior intervals which is referred to as the credible intervals. One way to construct a $100(1 - \alpha)\%$ credible interval is to form the equal-tailed interval, i.e., $I_\alpha = [\theta_{\alpha/2}, \theta_{1-\alpha/2}]$, where θ_z is the z -quantile of the posterior. However, this interval could be unnecessarily long and not representative of the posterior if the posterior distribution is asymmetric or even multi-modal. A better approach is to construct the Highest Posterior Density (HPD) intervals/sets. A $100(1 - \alpha)\%$ HPD set is defined as $I_\alpha = \{\theta : p(\theta|\mathbf{x}) \geq k\}$ where

$$k = \max \left\{ k : \int_{\theta: p(\theta|\mathbf{x}) \geq k} p(\theta|\mathbf{x}) d\theta = 1 - \alpha \right\}.$$

If the posterior is approximately uni-modal, then the HPD set is guaranteed to be the HPD interval.

Table 1 Posterior summary.

	<i>Mean</i>	<i>SD</i>	<i>Lower</i>	<i>Upper</i>
b_1	-3.626	0.337	-4.299	-3.049
b_2	-1.405	0.157	-1.716	-1.128

b_4	-1.823	0.188	-2.202	-1.500
b_5	-2.857	0.270	-3.405	-2.368
a	0.432	0.040	0.349	0.504

A real data example

We use the LSAT dataset provided by the *ltm* R package (Rizopoulos, 2015) for demonstration. The dataset was first described in Bock and Lieberman (1970). It contains dichotomous item responses from 1000 students to 5 items that are designed to measure a single latent trait. We fit the Bayesian 1PNO model with the Gibbs sampler described in the previous section. The posterior samples are then transformed back to the more common parameterization as in Eq. (1). The posterior summary are in Table 1. The first two columns are posterior means and posterior standard deviations. The last two columns are the lower limit and the upper limit of the 95% HPD intervals.

Posterior predictive model checking

A statistical model is essentially a set of assumptions. Before any inferences are drawn from the model, it is important to assess the fit of the model or, in other words, to check the degree to which the model fails to explain the data that are of our practical interest. This is particularly important to psychometrics where we are interested in inferring or measuring some theoretical attributes (e.g., intelligence) from observable quantities (e.g., responses to test items). A test item may not function as intended, and the subject may not respond to items as assumed by the model. Before making any conclusions about the attribute of interest, it is critical to evaluate the assumptions. Model checking procedures can help identify unreasonable assumptions which may be potentially mitigated in some way later.

The basic intuition of the PPMC method is that we can check the observed data against the replicated data predicted by the model using some statistics. The distribution of the replicated data is also referred to as the posterior predictive distribution, i.e.,

$$p(\mathbf{x}^{rep}|\mathbf{x}) = \int p(\mathbf{x}^{rep}|\boldsymbol{\zeta})p(\boldsymbol{\zeta}|\mathbf{x})d\boldsymbol{\zeta}, \quad (5)$$

where $\boldsymbol{\zeta}$ is a vector of all model parameters and $p(\boldsymbol{\zeta}|\mathbf{x})$ is the posterior distribution. Except for some simple models, finding the posterior predictive distribution requires sampling in general.

A statistic is a function of the data. Different statistics may describe different aspects of the data. Thus, it is important to choose appropriate statistics that reflect aspects of the model that are of interest to us. In this chapter, we follow the suggestions given by Sinharay (2005) and demonstrate the PPMC method using some most common and important statistics.

Observed sum scores

In many tests, ranking students is one of the most important objective. A model that does not predict the number of correct responses given by students well is very unlikely could rank students fairly. For the 5 dichotomous items in the example, there are 6 possible score categories. We observe a number of students within each score category. So the observed distribution of sum scores are $NC = (NC_0, NC_1, \dots, NC_5)$. Using the posterior samples produced by the Gibbs sampler, we can generate replicated datasets and compute the posterior predictive distribution of the sum scores. The result is in Fig. 3.

The observed sum scores all fall within the 80% HPD intervals of the posterior predictive distributions. For a given set of observed data and a chosen model, the choice of the level of HPD intervals has an effect on their lengths. The smaller percentages are associated with shorter intervals, therefore representing a more strict criteria for evaluating model fit. Compared to higher levels such as 90% or 95%, using a 80% HPD intervals leads to higher chances of detecting model misfits. In our case, the model does seem to be able to explain the distribution of number of correct responses well.

Polychoric correlation coefficient

An important assumption of the 1PNO IRT model is that discrimination parameters across all items are equal. To check this assumption we use the polychoric correlation coefficient. A polychoric correlation coefficient describes the correlation between

Fig. 3 The vertical bars represent the 80% HPD intervals of the predicted frequency distributions at each sum score, and the circles are the observed frequency of each sum score.

Fig. 4 The histogram describes the posterior predictive distribution of the variance of the polychoric correlations of the 5 items. The vertical line is the observed variance of the polychoric correlations. The observed is in a high posterior density region.

Fig. 5 The histogram describes the posterior predictive distribution of the odds ratio of an item pair. The vertical line marks the observed odds ratio of that item pair.

the normal variables derived from two observed ordinal variables - in our case, the total number of correct responses of a student and that student's item response to the j^{th} item. If the model is reasonable, then we would expect to see the polychoric correlations for all J items are similar or the variance of the polychoric correlations is close to 0. The results in Fig. 4 shows the variance of the observed polychoric correlations are very close to 0 and within a high density area of the posterior predictive distribution of the same statistic. Consequently, there is no evidence of this aspect of misfit of the model.

Odds ratio

The 1PNO IRT model assumes that item responses are independent of each other given latent abilities θ . This is also commonly referred to as the local independence (LI) assumption. If LI holds, the model should predict the odds ratio of any item pairs,

$$OR = \frac{n_{00}n_{11}}{n_{01}n_{10}}, \quad (6)$$

where $n_{kk'}$ denotes the number of students has a score k on the first item and a score k' on the second item. For 5 items, there are $\binom{5}{2} = 10$ pairs. For demonstration purpose, we plot the results of one item pair in Fig. 5. The observed OR is within a high density region of the posterior predictive distribution. The examined statistic does not show evidence of violation of the LI assumption for this pair of items.

Conclusion

Thanks to the development of general purpose Bayesian inference software such as the Stan, applied researchers now have access to a set of powerful tools to develop and estimate complex and sophisticated Bayesian models. While the software can help automate the Bayesian computation, it should be emphasized that all three steps outlined earlier in the entry are important and integral parts of the Bayesian modeling. Especially, the importance of evaluating model fit should not be overlooked. A model is a set of assumptions. Drawing inferences based on assumptions without checking them can be dangerous. Furthermore, the Bayesian modeling is really a continuous process where researchers iterate through the three steps. After the aspects of model-data misfits are identified in model fit evaluations, the model can be expanded and improved. In this entry, we offered a high level introduction to the basics of

Bayesian psychometrics. For a more detailed treatment of these introductory topics, readers may refer to Gelman et al. (2013) and Levy and Mislevy (2016).

Glossary

Invariance Evidence that a characteristic of interest holds over some set of conditions

Invariant item ordering Evidence that relative item difficulty ordering is consistent for all examinees, regardless of their latent variable location

Latent variable A continuous psychological variable that represents a construct of interest that cannot be directly measured. In item response modeling, items, persons, and other elements of an assessment procedure are hypothesized to hold locations on a latent variable

Nonparametric methods Descriptive and inferential statistical techniques that are not directly tied to a particular probability distribution

Modeling framework An approach to modeling quantitative data that provides researchers with a structure for analyzing the data and interpreting the results based on guiding principles or requirements

Mokken scale analysis A nonparametric item response modeling framework based on principles of invariant ordering

Monotonicity For dichotomous items, evidence that the probability for a correct or positive response is non-decreasing as examinee locations on the latent variable increase; For polytomous items, evidence that average ratings are non-decreasing as examinee locations on the latent variable increase

Nonparametric modeling framework Modeling framework for item response data in which the statistical techniques do not impose a specific mathematical structure on the shape of the relationship between the latent variable and the probability for a response (i.e., the item response function [IRF]) and instead rely on ordering requirements

Parametric modeling framework Modeling framework for item response data in which the statistical techniques impose a specific mathematical structure on the shape of the relationship between the latent variable and the probability for a response (i.e., the item response function [IRF])

Restscore Examinee sum scores minus scores from an item or a set of items of interest

Restscore group Groups of examinees with the same or similar restscores. Restscore groups are used to provide more statistical power for evaluating item properties such as monotonicity or invariant item ordering

Scalability Evidence that item response patterns correspond to what would be expected given relative item difficulty ordering

Nonparametric methods for modeling item responses: Mokken Scale Analysis

Nonparametric methods are descriptive and inferential statistical techniques that are not directly tied to a particular probability distribution. Nonparametric methods can be usefully applied to data that are used in educational research in order to address a variety of research questions. Nonparametric methods include standalone (a-theoretical) statistical tests (e.g., kappa coefficients), data exploration techniques (e.g., functional data analysis), as well as methods situated within modeling frameworks (e.g., Mokken Scale Analysis; discussed later in the article). The aim of this article is to provide an overview of nonparametric modeling frameworks that can be used to evaluate measurement instruments in educational research, such as achievement tests and attitude scales.

The structure of this article is as follows: The article begins with a description of nonparametric modeling frameworks in general. Then, a detailed discussion of Mokken Scale Analysis (MSA; Mokken, 1971), which is a theory-driven nonparametric modeling framework for social science measurement procedures, is provided with brief illustrations. The article continues with a brief overview of other nonparametric modeling approaches. The article concludes with a summary and discussion of the value of nonparametric modeling frameworks for educational research.

Nonparametric modeling frameworks for educational research

Modeling frameworks provide researchers with a structure for analyzing quantitative data and interpreting the results based on guiding principles or requirements. Particularly in the area of educational and psychological measurement, the general goal of modeling frameworks is to help analysts examine responses with the purpose of improving measurement procedures and informing the interpretation and use of the results from the measurement procedure. These approaches stand in contrast to data analysis techniques in which the ultimate goal is to describe relationships among variables or to replicate the structure of a dataset.

A variety of modeling frameworks for educational and psychological measurement are available that include both parametric and nonparametric techniques. Modeling frameworks based on *parametric* techniques impose a specific mathematical structure on the shape of the relationship between the latent variable and the probability for a response (i.e., the item response function [IRF]). For example, Rasch measurement theory (Rasch, 1960) is a parametric modeling framework in which the measurement models transform raw responses from an ordinal scale to an interval-level scale and require that IRFs conform to a logistic ogive (see Fig. 1). On the other hand, nonparametric modeling frameworks include, at most, ordinal requirements for the characteristics of the IRF. Nonparametric models do not involve mathematical transformations to achieve interval-level units. For example, models within the Mokken Scale Analysis (MSA (Mokken, 1971); framework allow IRFs to take on any shape as long as basic ordering requirements for individual items and groups of items are satisfied.

Parametric modeling frameworks are useful because their models result in convenient mathematical properties, including interval-level measures for items and persons, which are required for many statistical analyses. For example, interval-level estimates of item and person locations on a latent variable calculated using parametric IRT models can be applied to statistical techniques including Computer-Adaptive Testing and test equating. Although these applications are critical for many practical purposes, parametric modeling is not always necessary or appropriate for the measurement procedures that are used in educational research (Wind, 2017).

Parametric IRT models are characterized by several strong assumptions that are not always appropriate for educational and psychological measurement procedures (Santor and Ramsay, 1998; Junker and Sijtsma, 2001; Molenaar, 2001; Meijer and Baneke, 2004). For example, the appropriate interpretation of parameters such as examinee locations and item locations on a latent variable requires approximate adherence to the assumption that a logistic ogive (see Fig. 1A) accurately represents the relationship between examinee locations and item locations, and that this relationship holds for all examinees and all items. In addition, these models assume that the sample of examinees and items is sufficient to support precise parameter estimates for examinees and items that hold for the entire sample. Violations of these assumptions imply that the results from parametric IRT models may not have a meaningful interpretation, may be imprecise, and may not hold over replications of the measurement procedure. In addition, the

Fig. 1 Parametric item response function.

relatively stringent requirements of parametric IRT models may lead researchers to discard items for which model violations are observed at some locations on the latent variable, but not others (Santor and Ramsay, 1998; Meijer and Baneke, 2004). Reflecting on these challenges with parametric IRT models, Molenaar (2001) observed “there remains a gap ... between the organized world of a mathematical measurement model and the messy world of real people reacting to a real set of items” (p. 295). Although nonparametric IRT models are also imperfect representations of the “messy” nature of item responses, they provide researchers with tools for modeling these responses that provide additional flexibility that can be more appropriate and realistic for many contexts in which parametric IRT models may not be appropriate.

MSA is a practically useful approach to nonparametric IRT because it relies on requirements related to *invariance* in measurement procedures. The current article will focus on the nonparametric MSA modeling framework because it is a comprehensive nonparametric framework that can be usefully applied to evaluate measurement procedures in educational research. Following the discussion of MSA, some other nonparametric techniques that are relevant for educational research are briefly considered.

Mokken Scale Analysis framework

MSA is a probabilistic nonparametric framework for modeling responses from measurement procedures in the social and behavioral sciences. In his original presentation of MSA, Mokken (1971) discussed the usefulness of parametric IRT models in general, and Rasch measurement theory models (Rasch, 1960) in particular. He noted that these models have properties that are ideal for conducting mathematical analyses with social science data, but that they may not be appropriate for many practical applications. Mokken (1971) summarized the rationale for his approach to item response modeling as follows:

In vast areas of social research the application of parametric models may often be too far fetched. Their application presupposes a relatively deep insight into the structure of the variable to be measured and the properties of the items by which it can be measured. For these reasons it seems legitimate to try to find starting points for scaling models which do not rely too heavily upon specific parametric assumptions, as these lead to procedures of inference and estimation that are too pretentious and intricate for the level of information and the precision that can be claimed for the data used in actual measurement (p. 173).

In his presentation of MSA, Mokken noted that his scaling models are useful starting points for analyzing item response data before the application of parametric IRT models. However, Mokken (1971) and other researchers (e.g., Cliff and Keats, 2003; van Schuur, 2011) have also noted that nonparametric IRT models are also useful in their own right in contexts where an ordinal level of measurement is sufficient to inform the decisions that will be made based on a measurement procedure.

Working within the context of political science, Mokken proposed two nonparametric scaling models that reflect the emphasis on invariance that characterizes Rasch measurement theory, but that do not involve parametric transformations. Because of this shared emphasis on invariance, several researchers have discussed the theoretical and empirical similarities between MSA and Rasch measurement theory (e.g., Meijer et al., 1990; Engelhard, 2008). After their original presentation in the context of political science, MSA models earned popularity in contexts such as quality of life measurement (Vaughan et al., 2020), intelligence testing (Abdelhamid et al., 2020), clinical psychology (Tabares et al., 2020), physical therapy and rehabilitation (Rinkel et al., 2019), among others. In addition, researchers have recently applied MSA to educational assessment contexts, including multiple-choice assessments (e.g., Wind, 2016b) and performance assessments that involve rater judgments (Wind, 2016a, 2019).

Mokken Scale Analysis models

MSA includes two nonparametric IRT models: (1) the Monotone Homogeneity model and (2) the Double Monotonicity model. Mokken (1971) proposed the dichotomous formulations of these models in his original presentation of MSA. Extending these models, Molenaar (1982, 1997) presented polytomous formulations that have been applied across a wide range of social science contexts. The next sections introduce these models, followed by a discussion of recent variations on MSA models.

Monotone Homogeneity model

The first MSA model is the Monotone Homogeneity (MH) model. This model is characterized by three key assumptions: (1) *Unidimensionality*: One latent variable is sufficient to explain the variation in examinee responses; (2) *Local independence*: After controlling for the primary latent variable, there is no dependence between examinee responses to unique components of the measurement procedure (e.g., items), and (3) *Monotonicity*: As examinee locations on the latent variable increase, so does the probability for a correct or positive response. Both the dichotomous and the polytomous formulations of the MH model are characterized by these assumptions.

Because MSA models are nonparametric, the assumptions are evaluated using examinee locations calculated with *restscores*. Restscores are examinee total scores minus their score on the item of interest. Restscores avoid the problem that the item of interest is included the total score, such that researchers can evaluate each item independently. The MH model assumptions can be evaluated at the item level using restscores calculated as:

$$R_{ij} = X_{+i} - X_{ij},$$

Fig. 2 Item monotonicity plots. A: Two dichotomous items B: Two polytomous items.

where R_{ij} is the restsore for Examinee i specific to Item j , X_{+i} is the total score for Examinee i on all items, and X_{ij} is Examinee i 's score on Item j . In practice, researchers use restscores to evaluate adherence to the MH model assumptions with two primary indices: (1) numeric and graphical tests for monotonicity, and (2) scalability coefficients.

When it is applied to dichotomous data (scored such that $x = 0$ or $x = 1$) the monotonicity assumption states that as examinee locations on the latent variable increase, the probability for a correct or positive response ($x = 1$) does not decrease. **Fig. 2A** is a nonparametric IRF that illustrates a graphical approach to evaluating monotonicity for dichotomous Item 1. The x -axis shows *restscore groups*, which are subgroups of examinees with similar restscores who have been combined into groups to improve the statistical power of the test for monotonicity (see [Molenaar and Sijtsma \(2000\)](#) for a description of typical procedures for creating restsore groups in MSA). The y -axis shows the conditional probability for a correct or positive response specific to each restsore group. The solid line is the nonparametric IRF that shows the probability for a correct or positive response within each restsore group, and the light shading around the line shows a 95% confidence interval for these probabilities. Item 1 adheres to the monotonicity assumption because the probability for a correct or positive response is non-decreasing over increasing restsore groups.

When it is applied to polytomous data scored in categories $x = 0, \dots, k, \dots, m$, the monotonicity assumption states that as examinee locations on the latent variable increase, the probability for a rating in category k or higher ($x \geq k$) does not decrease. Although it is possible to evaluate item monotonicity within rating scale categories for polytomous items, most applications of MSA focus on overall item-level analyses. To evaluate monotonicity at the overall item level, analysts evaluate the extent to which average ratings on an item of interest are non-decreasing as examinee locations on the latent variable increase. Using restsore groups along the x -axis, **Fig. 2B** illustrates a graphical approach to evaluating monotonicity for polytomous Item 2, which was scored in four ordered categories ($x = 0, 1, 2, 3$). In this figure, the y -axis is the average rating observed within each restsore group. Item 2 adheres to the monotonicity assumption at the overall item level because the average rating observed within restsore groups does not decrease as restscores increase. In addition to graphical analyses, researchers can also evaluate item adherence to monotonicity using statistical hypothesis tests. For additional details about these tests, please see [Sijtsma and Molenaar \(2002\)](#).

Several properties are important to note regarding the nonparametric IRFs for the MH model, as illustrated in **Fig. 2**. First, the MH model IRFs can take on any shape as long as they adhere to the ordering requirement specified by the model; they do not have to conform to the logistic ogive shape that characterizes parametric IRT model IRFs. Second, when items adhere to the MH model assumptions, some important inferences can be made related to invariance. For the dichotomous model, adherence to the MH model implies *invariant person ordering over items*, which means that inferences about person ordering on the latent variable are consistent for all of the items in the scale. Specifically, the order of student total scores on the raw score scale (X_{+}) reflects their ordering on the latent variable (θ ; i.e., stochastic ordering on the latent variable [SOL]; [Hemker et al., 1997](#)). For the polytomous MH model, adherence to the MH model implies a weaker form of SOL. Specifically, *weak SOL* ([van der Ark and Bergsma, 2010](#)) means that examinee sum scores (X_{+}) can be used to divide the sample into two groups (low and high), and examinee classification within those groups can be used to identify students with low and high locations on the latent variable. Invariant person ordering is important because it means that the interpretation of examinee locations on the latent variable do not depend on the specific items or components of the scale used to measure them. As a result of these properties, researchers can check for adherence to the MH model assumptions to provide support for the interpretation and use of examinee sum scores with respect to the latent variable.

A second major indicator of adherence to the MH model is *scalability analyses*. Within the context of MSA, scalability analysis involves evaluating item responses for evidence that response patterns match what would be expected given item ordering. Specifically, scalability is evaluated by identifying *Guttman errors*. For dichotomous items, Guttman errors occur for a pair of items ordered such that Item C is easier than Item D, when a correct response to Item D is observed in combination with an *incorrect* response to Item C. For polytomous items, Guttman errors are identified at the rating scale category level, where the difficulty of each category is

calculated using cumulative category probabilities. MSA scalability coefficients were originally adapted from the scalability coefficients that [Loevinger \(1948\)](#) proposed for evaluating item pairs for evidence of Guttman errors. [Mokken \(1971\)](#) expanded Loevinger's coefficients to include scalability coefficients for individual items and pairs of items.

Scalability coefficients can be calculated using the ratio of observed-to-expected Guttman errors for individual items (H_i), pairs of items (H_{ij}), and a set of 3 or more items (H). The general form of these coefficients can be illustrated using the formula for the item-pair scalability coefficient:

$$H_{ij} = 1 - \frac{F_{ij}}{E_{ij}},$$

Where F_{ij} is the observed frequency of Guttman errors for the item pair made up of Item i and Item j , and E_{ij} is the expected frequency of Guttman errors given the marginal distributions of the responses for Item i and Item j . For individual items, scalability is calculated as:

$$H_i = 1 - \frac{\sum_{j \neq i} F_{ij}}{\sum_{j \neq i} E_{ij}},$$

For a set of three or more items, scalability is calculated as:

$$H = 1 - \frac{\sum_i F_{i,R(i)}}{\sum_i E_{i,R(i)}},$$

where $R(i)$ is the Restscore for Item i . It is also possible to calculate scalability coefficients using the covariances between pairs of items. For details about the covariance formulations of the scalability coefficients, please see [Sijtsma and Molenaar \(2002\)](#).

In applications of MSA, researchers frequently interpret these coefficients using critical values that [Mokken \(1971\)](#) proposed: $H \geq 0.5$: strong scalability, $0.3 \leq H < 0.5$: moderate scalability, and $H < 0.30$: weak scale. However, these critical values have not been thoroughly examined in methodological research, particularly for polytomous item responses. Instead of relying on critical values, researchers have recommended using standard errors (SE) for scalability coefficients ([Kuijpers et al., 2013](#)), interpreting scalability coefficients as continuous variables, and considering the implications of their values in the context of the specific application.

Double Monotonicity model

The second MSA model is the Double Monotonicity (DM) model. The dichotomous DM model ([Mokken, 1971](#)) and the polytomous DM model ([Molenaar, 1982, 1997](#)) share the same assumptions as the MH model, but include one additional assumption: (4) *Invariant item ordering* (IIO): Items have a consistent relative ordering for all examinees, regardless of their location on the latent variable. When data adhere to the DM model, a second important invariance property is observed in addition to invariant person ordering from the MH model: item ordering is invariant across examinees. This means that conclusions about the relative difficulty of a set of items are consistent for all examinees in a sample of interest. As a result, the DM model provides information about invariance related to person ordering and item ordering. These properties are useful for scale construction and evaluation when a consistent interpretation of item and person order on the latent variable is important for theoretical and practical purposes ([Ligtvoet, 2010](#)).

When it is applied to dichotomous item responses, the DM model assumption of IIO can be evaluated by examining the probability for a correct or positive response for *pairs* of items for evidence that the item ordering is consistent across the range of the latent variable. As in the MH model, an ordinal formulation of the latent variable is needed to evaluate IIO. Because the procedure for checking the DM model assumption of IIO is based on item pairs, restscores are calculated as follows:

$$R_{ijk} = X_{+i} - X_{ij} - X_{ik},$$

where R_{ijk} is the restscore for Examinee i specific to the item pair made up of Item j and Item k , X_{+i} is the total score for Examinee j on all items, X_{ij} is Examinee i 's score on Item j , and X_{ik} is Examinee i 's score on Item k . As with the MH model, examinee restscores are combined into restscore groups for the purpose of evaluating the DM model assumption of IIO.

In practice, researchers evaluate IIO for dichotomous items using graphical displays of nonparametric IRFs and statistical hypothesis tests. [Fig. 3A](#) illustrates nonparametric IRFs that were constructed for the purpose of evaluating IIO for the item pair made up of dichotomous Item 3 and dichotomous Item 4. In the figure, the x -axis shows restscore groups, and the y -axis shows the probability for a correct or positive response. For this item pair, IIO is observed because Item 4 is always easier (higher probabilities for a correct or positive rating) compared to Item 3 for all restscore groups. Importantly, the nonparametric IRFs can take on any shape as long as they satisfy the ordering requirements for the MH and DM models.

For polytomous items, IIO can be evaluated at the overall item level or within rating scale categories. Importantly, some researchers have observed that invariant ordering at the rating scale category level does not always correspond to invariant ordering for overall item scores ([Sijtsma and Hemker, 1998](#); [Ligtvoet et al., 2010, 2011](#); [Sijtsma et al., 2011](#)). As a result, researchers typically focus on invariance at the overall item level because this indicator has more practical utility compared to investigations of invariance for specific rating scale categories ([Ligtvoet et al., 2010](#)). Specifically, researchers have encouraged analysts to use the manifest IIO

Fig. 3 Invariant item ordering plots.

procedure (MIIO) that [Ligtvoet et al. \(2010, 2011\)](#) proposed. The MIIO procedure involves evaluating IIO for overall polytomous items, rather than evaluating individual rating scale categories for invariant ordering. [Fig. 3B](#) shows a MIIO plot for polytomous Item 5 and Item 6, both of which were scored in four categories ($x = 0, 1, 2, 3$). The x -axis shows restsore groups, and the y -axis shows the raw score scale. The IRFs show the average rating on each item observed within each restsore group. Item 5 and Item 6 adhere to IIO because Item 5 is easier (higher average ratings) compared to Item 6 for all restsore groups.

In practice, researchers typically evaluate IIO using plots such as those shown in [Fig. 3](#). In addition, researchers use statistical hypothesis tests that take into account the magnitude of violations of IIO to identify statistically significant violations that warrant additional investigation. For more details about statistical hypothesis tests for evaluating IIO, please see [Sijtsma and Molenaar \(2002\)](#).

Software for MSA

Several software programs are available within which researchers can apply MSA models. Specifically, [Molenaar and Sijtsma \(2000\)](#) presented *MSP5*, which is a standalone software program that researchers can use to analyze data with MSA models. However, *MSP5* is no longer being updated to reflect recent developments in MSA. In addition, a Mokken scaling module has been developed for use with the Stata software program ([Hardouin et al., 2011](#)). Finally, researchers can conduct MSA using the *mokken* package for the R software program ([van der Ark, 2007, 2012](#)). This package is frequently updated to reflect methodological developments in MSA.

Variations on MSA

Recently, researchers have proposed several variations on MSA that facilitate analyses that are better suited to specific data collection designs or research questions than the original dichotomous and polytomous MSA models. For example, [Koopman et al., 2016; Koopman et al., 2020; Koopman et al., 2020](#)) and colleagues have presented adaptations of MSA statistics that are designed for use with multi-level (i.e., nested) data structures. In addition, [Wind \(2016a, 2019; Wind and Schumacker, 2017\)](#) presented an adjacent-categories adaptation of MSA indices that can be used to identify rating scale category disordering in contexts where this information is relevant, such as in rater-mediated educational performance assessments.

Other nonparametric approaches

This article focused on MSA because it is a nonparametric approach that is situated within a modeling framework that provides guidance for interpreting analyses based on a measurement theory. However, other nonparametric techniques are available that researchers can use to analyze educational research data that are not suited for analysis with MSA, in contexts where a measurement framework is not needed for modeling item response data, or in contexts where an exploratory approach is needed before measurement-focused analyses are conducted.

For example, a number of nonparametric statistical tests are available that are not based on any particular modeling framework but provide insight into a variety of research questions that may be of interest in educational research. For example, kappa statistics ([Cohen, 1968; Berry and Mielke, 1988; Schuster, 2004](#)) provide information about rater agreement, but these statistics are not based on a measurement framework.

Another type of nonparametric analysis that is useful in educational research is functional data analysis ([Ramsay and Silverman, 2005](#)). Functional data analysis provides valuable exploratory tools for examining data in a variety of contexts, including a number of variables that are relevant in educational research. Among functional data analysis techniques, kernel smoothing ([Ramsay, 1991](#);

Mazza et al., 2014) can be used to estimate and visualize response functions for item response data in educational research. Although functional data analysis is not directly tied to a measurement framework, it offers insight into response patterns and other characteristics of data that can help inform the interpretation and use of measurement instruments and can also inform future analytic decisions.

Summary and conclusions

The purpose of this article was to provide an overview of nonparametric modeling frameworks that are useful for examining the properties of measurement instruments in educational research. First, a general consideration of modeling frameworks was presented and a distinction was made between parametric and nonparametric modeling frameworks for analyzing responses to educational and psychological measurement instruments. The major focus of the article was on Mokken Scale Analysis (MSA; Mokken, 1971) because MSA is a theory-driven nonparametric modeling framework that offers several useful indices for evaluating measurement instruments that are particularly useful in educational research. An overview of MSA was provided, including a description of the two major MSA models and procedures for checking their assumptions. The article concluded with a brief discussion of other nonparametric analysis techniques that may be relevant for educational research.

The major conclusion from this article is that nonparametric modeling frameworks such as MSA are available that can provide educational researchers with theory-based analytic techniques for evaluating their measurement instruments but that do not rely on potentially inappropriate parametric techniques. These methods can be used as a standalone procedure and they can also be used to supplement parametric analyses either as a preliminary analytic step or to provide additional information beyond what is captured by parametric models. These nonparametric frameworks include numeric and graphical techniques for evaluating the properties of measurement instruments in educational research that can provide insight into the degree to which instruments exhibit important measurement properties, such as invariant item and person ordering.

Introduction

What is *principled assessment design*, or PAD? And, where do those principles come from? One part of the answer to these questions is that the current usage of the term arose in the impact of cognitive psychology on testing, principally in education, but also in psychology. Under the impetus of writing by figures such as [Glaser \(1981\)](#), and [Snow and Lohman \(1989\)](#), new demands were made of tests to respond to criticisms like the following from a very influential National Research Council (NRC) Committee Report:

The central problem ... is that most widely used assessments of academic achievement are based on highly restrictive beliefs about learning and competence not fully in keeping with current knowledge about human cognition and learning. Likewise, the observation and interpretation elements underlying most current assessments were created to fit prior conceptions of learning and need enhancement to support the kinds of inferences people now want to draw about student achievement.

NRC (2001, pp. 2–3).

The suggested solution was to base the logic of the measurement that is embodied in the test in the theories and practices of cognitive psychology. In one sense, this was just a re-statement of an older adage about the question of test validity—that a test is valid if it does what it is supposed to do—but the suggestion is that cognitive psychology should be the source of the property that is being measured by the test. However, it was also a serious challenge to the then-dominant role of “content” in defining the goal of testing, a goal that is so centrally embodied in the mastery-testing formulation of pedagogic design ([Bloom, 1981](#)).

With the help of some forward thinking among psychometricians (as argued, for example, by [Mislevy \(1996\)](#) in his aptly-named paper “Test theory reconceived”), the NRC established a Committee to acknowledge and advance this perspective ([NRC, 2001](#)). The Committee established a common-ground delineation of what aspects should be incorporated into this perspective, which they referred to as foundations. In the words of the Committee:

First, every assessment is grounded in a conception or theory about how people learn, what people know, and how knowledge and understanding progress over time. Second, each assessment embodies certain assumptions about which kinds of observations, or tasks, are most likely to elicit demonstrations of important knowledge and skills from students. Third, every assessment is premised on certain assumptions about how best to interpret the evidence from the observations in order to make meaningful inferences about what students know and can do (p. 16).

This is illustrated in the NRC Assessment Triangle shown in [Fig. 1](#), with the three foundations succinctly labeled as Cognition, Observation, and Interpretation. The foundations then, are seen as constituting a guide for “the process of collecting evidence to support the types of inferences one wants to draw ... referred to as *reasoning from evidence* [emphasis in original]” ([Mislevy, 1996](#), p. 38). These ideas then constitute a founding attempt at laying out the principles in PAD. The fact that the Committee labeled them as “foundations” reflects the implicit view that they also constitute a philosophical foundation for the measurement involved in the assessments (see [Mari et al. \(2021\)](#) for a perspective on this). Generally, the collection of such evidence is referred to in the

Fig. 1 The National Research Council (NRC) assessment triangle.

testing literature as test validity, and the appropriate standards for current professional practices regarding such evidence is delineated in the “Testing Standards” (American Educational Research Association et al., 2014). Although these Standards are designed to be industry-wide, and hence apply to many forms and varieties of assessment that would not be seen as conforming to PAD ideas (or even be vaguely associated with such), in the main, the types of validity evidence listed in the Testing Standards are very consistent with the perspectives described in this article, which are much influenced by the newer perspective described above. For example, to read an account of how the strands of validity evidence given in the Testing Standards can be related to one of the PAD approaches—the BEAR Assessment System, described in the next section—see chapter 8 of Wilson (2004).

Some reflection of the influence of the NRC Assessment Triangle conceptualization can be seen by considering two subsequent reviews of the topic of principled assessment designs (Ferrara et al., 2016; Nichols et al., 2016). Both are useful and insightful accounts, and we acknowledge a debt to their work. We have summarized their delineations of the topic in Table 1—we will not go into depth on their systems but save this level of detail for the specific PAD approaches discussed below. As can be seen, Ferrara et al. (2016) postulate five “foundation” elements of PAD, and these can be readily assigned to the three vertices of the NRC Assessment Triangle, with the first three aligned to the Cognition vertex. In contrast, the Nichols et al. (2016)’s system is composed of three elements, and each of these is quite consistent with one of the three NRC vertices. In addition, both systems argue that the elements should be seen as part of a larger whole—each contributing to the crucially important validity argument, as is the case for the NRC Assessment Triangle.

In the sections that follow, we will first give a detailed example of one particular PAD approach, pointing out how the NRC foundations play a central role in the structure of that approach. This is followed by descriptions of several other selected PAD approaches to show the diversity of ways in which the idea of a principled design can be exploited, while still maintaining a similarity with the NRC formulation. The article finishes with a section containing a discussion of links beyond assessment, and some final concluding remarks.

The BEAR assessment system

The BEAR Assessment System (BAS; Wilson and Sloane, 2000) uses four “building blocks” to address the PAD challenges for good assessment: (a) construct map, (b) items design, (c) outcome space, and (d) measurement model. As expressed in Fig. 2, these building blocks are seen as being used in a specific cyclical sequence during assessment development, but the cycle may also iterate during development. These four building blocks embody the three foundations from the NRC Assessment Triangle. In other words, the foundations are also seen as being principles for assessment development. The match, in sequence, is (a) construct map to Cognition, (b) items design to Observation, and (c) outcome space and measurement model (together) to Interpretation. This matching is enlarged upon below, in the respective subsections of this section. For a detailed account of an instrument development

Table 1 A summary of three different, but related, systems for Principled Assessment Design (PAD).

NRC (2001): <i>Assessment triangle</i>	Nichols et al. (2016): <i>Three common characteristics of PAD approaches</i>	Ferrara et al. (2016): <i>Five foundation elements and one organizing element of PAD approaches</i>
Cognition	Construct-centered approach	Clearly defined assessment targets Statement of intended score interpretations and uses Model of cognition, learning, or performance
Observation	Explicit design decisions and rationales	Manipulation of assessment activities to align with assessment
Interpretation	Engineering toward intended interpretations and uses	Aligned measurement models and reporting scales
Overall evidentiary reasoning goal	Evidentiary coherence to enhance validity	Ongoing accumulation of evidence to support validity arguments

Fig. 2 Four building blocks in the BEAR Assessment System (BAS).

process that works through these building blocks, see [Wilson \(2004\)](#). Below, each of these building blocks is considered in turn, and related to the PAD challenges.

The construct map (building block 1)

The construct map (see [Fig. 3](#) for an example) represents a cognitive and developmental perspective on student learning (corresponding to Cognition—the first, top vertex of the NRC Assessment Triangle). Rather than conceptualizing learning as simple as a matter of acquiring quantitatively more knowledge, skills, and understandings, learning is conceptualized in BAS as progress along the road to higher levels of cognition where new knowledge is linked to existing knowledge, and as less sophisticated

<i>Functions Learning Progression: Making Connections Across Multiple Representations of Mathematical Functions</i>		
Level of sophistication:	Student is able to:	Response to items:
(5) Extended Abstract	Make connections not only within the given subject area, but also beyond it, able to generalize and transfer the principles and ideas underlying the specific instance.	- Predict, explain, and synthesize their understanding to a real-world context. - Solve non-routine problems including non-algebraic functions.
(4) Relational	Demonstrate understanding of the significance of the parts in relation to the whole.	- Compare/contrast information given in multiple representations of functions to demonstrate understanding of the content. - Recognize which representations to choose for the context. - Select representations and move fluently among them to achieve a solution.
(3) Multistructural	Make a number of connections, but the meta-connections between them are missed, as is their significance for the whole.	- Make connections across more than two representations (e.g., symbolic, tabular, graphic, and verbal representations). - Recognize more than one relevant feature of a functional relationship
(2) Unistructural	Make simple and obvious connections, but their significance is not grasped.	Make pair-wise connections between representations.
(1) Prestructural	Acquire bits of unconnected information, which have no organization and make no sense.	- Interpret graphs where both variables have to be interpreted, or where time as independent variable. - Demonstrate understanding of function in one representation.
(0) Prealgebraic	Acquire prerequisite skills.	Demonstrate understanding of: - functional dependence, where a change in one variable affects another variable. - continuous variables (time, distance) and dichotomous variables (hot or cold). - relative order and measurement to define variables.

Fig. 3 Functions construct map (Note: read from bottom to top).

understandings are substituted by deeper understandings. It is assumed that learning can be described and mapped as a progression toward qualitatively richer knowledge, higher-order skills, and deeper understandings. This progression is not necessarily along a single path, but may be represented as progression along multiple paths, in say, a multi-dimensional representation.

These progression paths are thought of as developing variables of student ability. They are drawn, in part, from research on the foundational cognitive structure of the assessment domain, and also from educators' professional views about the nature of higher and lower levels of performance, and how it is manifested in student work. An important component of that is the empirical research on how students respond to instruction or perform in practice (NRC, 2001), including in typical testing situations, as well as in classroom-embedded contexts. The construct map can be seen as a "boundary object" mediating between the assessment and the instruction that a teacher might devise based on the assessment outcomes, but also a mediator between the assessment developer and the curriculum structure that defines the context in which the assessment will be used (Fisher and Wilson, 2019; Lehrer et al., 2014). An example using the "Functions" construct from an assessment of college-readiness in mathematics (Wilmot et al., 2011) is described below to illustrate this.

The Functions construct was conceived using the Structure Of the Learning Outcome (SOLO) taxonomy (Biggs and Collis, 1982), a conceptual framework that is used to assess student ability to make relational connections within and across subject areas. The aim was to model multiple representations of mathematical functions, and then design an assessment that comports with that structure. The typical application of the SOLO taxonomy has five levels of student understanding. This assessment extended the taxonomy by adding a sixth level at the bottom called "Prealgebraic." The Functions Learning Progression consists of a single construct map shown in Fig. 3—note that this is somewhat unusual, as most learning progressions are conceived as being more complex (Wilson, 2009)—it has been chosen as an example because it is relatively easier to compress it into a short article (see in Schwartz et al. (2017) for an example of a more typical, complex learning progression consisting of several inter-related construct maps). Student responses are classified from lowest to highest, representing increasing sophistication in student understanding of the connections among mathematical functions. For details about these levels and the expected student responses, see Wilmot et al. (2011, pp. 265–266).

Creating such a construct map is not a trivial task—see Wilmot et al. (2011) for an account of the developmental steps involved in developing this one. However, having succeeded in formulating a set of construct maps within a given curriculum, the task of dealing with the challenges raised in the first part of this article can be readily assayed, though the steps are also not at all trivial. This approach assumes a match between instruction and assessment, which will be addressed next.

The items design (building block 2)

The items design, which is a plan for systematic observations (the second vertex of the NRC Assessment Triangle) using assessment tasks or activities, along with the construct maps, to establish the match between the instruction and assessment in BAS. Essentially, the core framework for the curriculum and instruction must be the same as the set of construct maps for the assessments. This is not to imply that the curriculum description should completely encompass the assessment, nor that the curriculum should be driven by the assessment, but instead that the two (assessment and instruction) need to be aligned. More specifically, the range and contents of the instructional practices used in the curriculum should be reflected in the assessment tasks, and the assessment tasks must be placed in appropriate spots to adhere to the "rhythm" of the instruction—they must occur when it makes instructional sense to include them, typically be at where instructors want to know how much progress their students have made on a specific topic. This brings the content-depth and topic-relevancy of curriculum development into assessment, and at the same time, instills the discipline and hard-headedness of assessment data into the design of instruction.

BAS can utilize a wide range of styles of assessment tasks, including tasks that involve student readings, laboratory exercises, interactive exercises, individual and group challenges, and data interpretation questions. The test based on the Functions construct map was composed of 12 constructed response items (for a full text of the test [in 6 different administration forms], see Wilmot (2008, pp. 173–302)). Students were asked to write their responses with words, algebraic formulas, and/or numbers. An example item, the Hexagon Pattern task, is shown in Fig. 4. If student work is generated or students can be observed at work, and this performance can be scored by matching it to the construct maps, then it is amenable for BAS regardless of the form of instruction. Developing both the instructional materials and the assessment tasks at (roughly) the same time is a good way to make this happen—by adapting and/or cloning good instructional sequences to produce assessable responses, and/or by developing successful assessments into full-blown instructional activities.

The outcome space (building block 3)

For instructors and students to use information from the assessment tasks and the BAS reports, it must be represented in terms of the levels in the construct maps. This is the first part of interpretation (the third vertex of the NRC Assessment Triangle). For selected response items, the outcome space is usually directly related to subsets of the selections, but for open-ended items, the situation is more complicated—open-ended tasks (with written, performance, or product outputs) must be speedily and reliably scorable. Thus, for open-ended tasks, one must ensure that the outcome space (or the "rubric") is either efficiently scorable by relevant professionals, such as teachers, students themselves, readers, teaching assistants and/or instructors, or scorable by machine, say, using web-based interfaces with real-time delivery of instructional material and feedback.

The application of the outcome space related to a specific construct map for a specific item is called a scoring guide. To make scoring guides more readily useable, instructors and students need concrete examples (called "exemplars") that show the rating

1. For the following geometric pattern, there is a chain of regular hexagons (meaning all 6 sides are equal):

- 1a.) Complete the table showing the number of hexagons in a chain and the perimeter (number of outside edges).

NUMBER OF HEXAGONS	PERIMETER
1	6
2	10
3	
4	
5	

- 1b.) Describe the process for determining the perimeter for 100 hexagons, without knowing the perimeter for 99 hexagons.

- 1c.) Write a formula to describe the perimeter for any number of hexagons in the chain (it does not need to be simplified).

- 1d.) Explain why you think your formula in (1c) is correct.

- 1e.) Suppose instead of regular hexagons, you form a chain with regular n -gons (where n is any number of sides). Describe the process for determining the perimeter for any number of regular n -gons in a chain.

- 1f.) Write a formula to describe the perimeter for any number of regular n -gons in a chain (it does not need to be simplified).

- 1g.) Explain why you think your formula in (1f) is correct.

Fig. 4 Hexagon Pattern task.

Connection Construct	GP-1 Exemplars
EA - Extended Abstract: Applies knowledge of functions for hexagons to a generalizable formula for n-gons.	Symbolic function for n-gon (1g) is correct and related to the symbolic function for hexagon (1c).
R - Relational: Relates information from hexagons to determine functions for n-gons.	Verbal function for n-gon (1e/1g) is correct and related to verbal function for hexagon (1b).
MS - Multistructural: More than two functions (tabular, verbal, symbolic) are clearly connected.	Table (1a), verbal description (1b), and equation (1c) are correct and connected.
US - Unistructural: Two functions are connected.	Table (1a) and equation (1c) is connected OR Table (1a) and verbal description of 100 hexagons is connected (1b) (Note: Verbal description must demonstrate knowledge beyond “adding four”).
PS - Prestructural: One function is correct.	Table (1a) is correct.
PA - Prealgebraic: One function is partially correct.	Table (1a) is partially correct (Note: Student may mention “adding four” as the only substance to the problem).
OT - Off Target	Nothing is correct. Makes no sense.
DK - Don’t Know	Writes “I don’t know”.
NR - No Response	Blank.

Fig. 5 Scoring guide for the Hexagon Pattern task (Note: read from bottom to top).

of specific samples of student work. These examples should illustrate what an instructor might expect from students at varying levels of development along each variable (i.e. at the different levels of the construct map). It turns out that this is also a critical element of how raters learn to understand the rationale of the construct maps and scoring guides. Fig. 5 shows a summary of the “scoring guide” for the Hexagon Pattern task (from Fig. 4), which shows how student responses are coded into the six construct map levels from Fig. 3, and hence would be scored as shown in Fig. 3. Note that in Fig. 5 there are a few more codes for responses that are only partial, and these would generally be scored as zero, alongside Prealgebraic. Beyond this, genuine samples of student work, scored and moderated by project members, are helpful as a resource for each activity—they illustrate typical responses for each score level, as well as atypical responses which can require careful consideration by a rater.

The measurement model (building block 4)

This is the technical end of the measurement development, and also the second part of interpretation (the third vertex of the NRC Assessment Triangle). The approach adopted here is to use the special version of item response modeling (IRT), known as the Rasch model (Rasch, 1980). In particular, the techniques pioneered by Adams et al. (1997a,b), which are broadly used in the Program for International Student Assessment (PISA) testing, are applied. These measurement models are well-developed enough for use in classroom-based assessments in a fairly routine and feasible way, with accompanying software that is available to be used by district- and school-based professionals and classroom teachers (Wilson et al., 2019). Quality control information is available as an output from these models. The output can be used to estimate where individual students are located on the Functions variable using a map, called a Wright Map, as shown in Fig. 6. The analyses for these Wright Maps were performed using the ConQuest software (Adams et al., 2020), which implements an expectation-maximization (EM) algorithm for the estimation of multi-dimensional Rasch-type models.

In Fig. 6, the Functions construct map levels are shown in the first column on the left-hand side. The second column from the left shows the units of the Functions scale (in logits). The third column from the left shows the estimated distribution of a set of students who responded to the Functions items in a data set gathered as part of the field trial of the test. The right-hand side of Wright Map is devoted to the items. There are eight items, named at the top of the first eight columns from the right.¹ Within each of those columns, the calibrated difficulty thresholds between the levels of the respective item are shown.

¹Since there is not enough room on the Wright map to show all 12 items, eight of the 12 items are represented on the right side, with their respective titles written across the top of the map. The Equivalent Functions item is similar to the missing four items on the map.

College Readiness Assessment – Wright Map			Distribution of item difficulty (n=8)							
Level on the Connections Construct Map	Estimate	Distribution of student proficiency (n=688)	HEXAGON PATTERN	EQUIVALENT FUNCTIONS	EDUCATIONAL ACCOMPLISHMENTS	GENDER GAP	COST OF POSTAGE	STAIRCASE TOOTHPICK	24 HOUR CRUDE OIL	100 YEARS CRUDE OIL
Extended Abstract (EA) Relational (R)	4						R		EA	EA
	3				EA	MS		MS US		
	2	X XXX		R	R				R	R
Multistructural (MS) Unistructural (US)	1	XXXXXX XXXXXXXXXX XXXXXXXXXXXXXXXXXX XXXXXXXXXXXXXXXXXX -XXXXXXXXXXXXXXXXXXXX XXXXXXXXXXXXXXXXXXXX XXXXXXXXXXXXXXXXXXXX XXXXXXXXXXXX	EA R		MS	US	MS		MS	MS
	0		MS US	MS	US	PS	US PS	PS PA		US
				US

	-2				PA	PA				PS PA
EACH X REPRESENTS 4 STUDENTS, EACH ROW REPRESENTS .255 LOGITS										

Fig. 6 Wight map for the functions construct.

The Wright Map can be used for multiple purposes. The main idea is to use it to show how the items relate to the students. In this Figure, for example, one can note that the top levels (denoted by “EA”—see Figs. 3 and 5 for the meaning of these abbreviations) for two of the items, “24 Hour Crude Oil” and “100 Years Crude Oil,” are located above the highest student location. This means that it is very unusual for students to respond at those levels. In contrast, one can consider the lower end of the map, and see that it is very likely that some students responded at level PA or below. Most students have responded at about the US or MS levels.

The Wright Map is just one aspect of the functioning of the Partial Credit Model (Masters, 1982). It can also be used to control instructor rating consistency, and to maintain a meaningful measurement scale throughout the school year. This regularity in measurement makes the information from the items more useful for instructors in the classroom. Based on the Wright Map, advice on “next steps” in instruction can be generated by and for teachers. Many types of maps are available, derived from the analysis of student data collected in coursework. For example, Wright Maps can be used to track and assess student progress, and to exemplify the skills that a student has not yet mastered or is working on. Teachers can illustrate students’ progress with respect to the goals and expectations of the course by locating students’ performance on the scale in the map. The map can also be used to inform the planning of instruction. Wilmot (2008) interviewed a small sample of teachers to examine the usages that they made of the Wright Maps and associated reports of results for the Functions test. In her summary of her interviews, she noted that the maps helped teachers with the following activities: (a) checking student progress, (b) making instructional decisions, (c) seeing learning as a trajectory, and (d) planning curriculum across years. Further details and examples can be found in chapter 5 of her dissertation (Wilmot, 2008, pp. 126–131).

The BAS approach was originally envisaged in the context of classroom assessments (Kennedy, 2005; Wilson, 2018) and formative assessments embedded in curricula (Wilson and Sloane, 2000). Recent examples illustrating this can be found in the subject areas of reading (e.g. Dray et al., 2019), science (e.g. Junpeng et al., 2018; Metz et al., 2019; and for a Next Generation Science Standards [NGSS] application, Morell et al., 2017), mathematics (e.g. Arneson et al., 2019; Lehrer et al., 2014), and 21st century skills (e.g. Siddiq et al., 2017). BAS has also been applied in large-scale assessments in the topic areas of collaborative problem solving (Zhang et al., 2018), and information and communications technology (Wilson et al., 2018). All of these are in typical testing situations (both online and pencil-and-paper), but its largest application to date has been to an observational system for tracking child development in five early childhood and kindergarten learning domains (the Desired Results Developmental Profile [DRDP], see <https://www.desiredresults.us>), which is used in several US states, most conspicuously in California. Although initially proposed for cognitive assessments, BAS has also been found to be useful in the affective domain (e.g. Koo et al., 2021; Hermisson et al., 2019; Rocca et al., 2018), and in assessing teacher skills and behaviors (Duckor and Holmberg, 2017; Duckor et al., 2017).

Selected principled assessment design approaches

In this section, we give an account of selected PAD approaches, and briefly point out how they are consistent with and aligned to the NRC formulation in Fig. 1. This account is based, in part, on the earlier work of Ferrara et al. (2016).

Evidence-centered design

Evidence-Centered Design (ECD)² uses a logical and systematic approach based on evidentiary arguments to design, implement, and deliver educational assessments (Almond et al., 2015; Mislevy and Haertel, 2006; Mislevy and Riconscente, 2006; Mislevy et al., 2003b). Stemming from Messick (1989)’s views on validity—defined as “the degree to which empirical evidence and theoretical rationales support the adequacy and appropriateness of interpretations and actions based on test scores” (p. 13)—ECD focuses on the process of reasoning using evidence from observations of what students say, do, or make in a particular testing situation, to make broader inferences about their knowledge, abilities, or other attributes. What this implies is that an assessment needs to begin around (a) the inferences to be made, (b) the observations that are needed to support those inferences, and (c) the chain of reasoning that links the observations to the inferences. This shows the clear alignment of ECD to the three-part NRC Assessment Triangle. In this way, the ECD framework “helps one understand the connections among an assessment’s purpose, a conception of proficiency in the domain, the evidentiary argument, the design of the assessment elements, and operational processes,” and “organizes thinking about domains, purposes, and delivery capabilities in a way that leads to coherent assessments” (Mislevy et al., 2003b).

Drawing on ideas from architecture and software engineering, ECD enhances the NRC Assessment Triangle model to encompass the entire assessment design and development process by viewing it in terms of five “layers” or clusters of activities: (a) domain analysis, (b) domain modeling, (c) conceptual assessment framework, (d) assessment implementation, and (e) assessment delivery. Generally, across the layers, ECD follows a chain of reasoning starting with an analysis of the domain of knowledge, skills, or attributes of interest. This is followed by the specification of the claims to be made based on the test, the decision on the evidence to support the claims, the development of tasks to provide the required evidence, the assembly of an appropriate set of tasks to support the claims with sufficient evidence, the establishment of rules for scoring and score aggregation to extract the necessary evidence, and

²This gives just a brief overview of ECD—for greater depth, the reader is directed to the article on “Evidence Centered Design” by Chengbin Yin and Bob Mislevy in this volume for more details.

a description of the explicit logic links across the entire process. While the layers may suggest a sequential design process, each layer may be executed and tweaked independently without affecting the rest of the layers, and yet, the different layers are closely inter-related. Consequently, as for BAS, the ECD process is iterative—problems that surface in a later layer may require us to return to and refine an earlier layer, or to make changes across layers.

As the first stage in the assessment design, the domain analysis layer collects background and fundamental information about the domain of interest, usually with the help of subject-matter experts. The analysis provides understanding of the valued knowledge and skills in the domain, and the situations that elicit the use of such knowledge and skills. The second domain modeling layer organizes the information gathered from the investigation in the domain analysis to focus on a selection of aspects of the domain, including claims, data, and warrants, in order to construct an assessment argument. This transitions to more precise specifications for the assessment system (e.g. item types, delivery system, scoring scheme, measurement model) in the third conceptual assessment framework layer. The conceptual assessment framework, as depicted in Fig. 7, is akin to the “blueprint” for the assessment. It comprises several models, such as the student (or proficiency) model, task model, evidence model, and assembly model, which are connected through key elements called student model variables, task model variables, observable variables, and work products. The first three models show the link to the NRC Assessment Triangle—the student model defines the variables related to the knowledge, skills, or attributes that the assessment is trying to measure; the task model provides a description of the task characteristics that would elicit the desired observable behavior or product; and the evidence model provides a bridge across the student and task models by describing the responses to the task that would provide evidence on the knowledge or skill of interest. The assembly model then describes what the test would look like as a whole, and makes the linkages among claims, evidence, and tasks explicit. The next layer is assessment implementation, which concerns the operational elements specified in the conceptual assessment framework layer, including item writing, scoring mechanisms, and measurement models. Finally, the assessment delivery layer provides the interface for task interaction, performance evaluation, and scoring. It comprises four principal processes: activity selection, task presentation, response processing, and summary scoring.

The use of evidentiary reasoning in ECD can be applied to a wide variety of assessments, from traditional paper-and-pencil assessments based on classical test theory, to more complex computer-based assessments that use advanced measurement models. Importantly, ECD does not replace traditional test development; instead, ECD augments traditional test development. ECD has been widely implemented in various assessment initiatives by SRI International, Cisco Systems, Educational Testing Service (ETS), and the College Board, as well as in statewide assessment programs (e.g. National Center and State Collaborative [NCSC], Partnership for Assessment of Readiness for College and Careers [PARCC], Smarter Balanced) under the Race to the Top initiative (Ferrara et al., 2016). The ECD approach has also been formulated as Evidence-Centered Game Design (ECgD; Mislevy et al., 2014) to focus on building principled assessments within gaming situations. More recently, the Next Generation Science Assessment (NGSA, see <http://nextgenscienceassessment.org/>) project has adopted ECD as the design framework to develop formative assessments aligned with the NGSS. An open-source version of the full ECD package has also been established—the Principled Assessment Designs for Inquiry (PADI, see <https://padi.sri.com/>).

Fig. 7 Principal design objects of the Evidence-Centered Design (ECD) conceptual assessment framework. Note. These models are a bridge between the assessment argument and the operational activities of an assessment system. Looking to the assessment argument, they provide a formal framework for specifying the knowledge and skills to be measured, the conditions under which observations will be made, and the nature of the evidence that will be gathered to support the intended inference. Looking to the operational assessment, they describe the requirements for the processes in the assessment delivery system. Reproduced from Mislevy et al. (2003a) with permission from John Wiley and Sons.

Cognitive design system

The Cognitive Design System (CDS) is a framework that “centralize(s) the role of cognitive theory in [the development of] ability and achievement tests” (Embretson, 1998; Embretson and Gorin, 2001). According to Embretson (1994), there are several advantages in applying cognitive design to testing: (a) cognitive theory elaborates the constructs and processes that are involved in item solving, and thus supports construct validity of a test; (b) the correlations of test scores with other variables (or nomothetic span) can be explained by cognitive theory; (c) item design moves from an artistic process to a scientific process that reflects the cognitive theory influencing the processing requirements in the task; and (d) cognitive theory allows items with difficulties that are more precisely targeted to be developed, thereby increasing the efficiency of test development. Consequently, CDS has the following properties: “(1) test content is prescribed by explicit principles; (2) score meaning is linked to underlying cognitive processes, rather than just to correlations with other measures; (3) item parameters represent the sources of cognitive complexity in the item; and (4) abilities are linked to the processes that underlie task difficulty.”

CDS comprises a conceptual framework and a procedural framework. The conceptual framework distinguishes two empirically separable aspects of construct validity: (a) construct representation, and (b) nomothetic span. Construct representation “concerns the meaning of test scores,” and “is elaborated by understanding the processes, strategies, and knowledge [structures] that persons use to solve items” (Embretson, 1998). It is supported by research from cognitive psychology. For example, empirical data from modeling item difficulty in terms of accuracy and response time can be used to identify elements of the stimuli that can be manipulated to vary the cognitive demands in the assessment task. On the other hand, nomothetic span “concerns the utility [or significance] of the test for measuring individual differences,” and “is elaborated by the correlations of test scores with other measures” (Embretson, 1998). Importantly, the correlations are a consequence of construct representation. In other words, test meaning precedes test significance. This is in contrast with the traditional conceptualization of construct validity where test meaning is elaborated by the external correlations (Cronbach and Meehl, 1955). Since meaning is established after the test is developed, the correlations provide little information about how to improve the test design.

The CDS procedural framework, as outlined in Table 2, specifies a sequence of developmental stages that integrates cognitive theory into the test design. While the stages are presented sequentially, the actual test development process is iterative, that is, if problems are surfaced in a particular stage, one may need to re-visit and refine the earlier stages. Embretson and Gorin (2001) described seven key procedural steps for CDS: (a) specify the goals of measurement in terms of construct representation and nomothetic span; (b) develop a cognitive model that consolidates the relevant processes, strategies, and knowledge structures; (c) identify the task features that can be manipulated to vary construct representation by influencing the cognitive processes, strategies, and knowledge structures required for item-solving, using research from cognitive psychology based on research and theory for the particular item type, operationalization of the item features that affect item solving processes, and empirical evidence of the impact of those features on psychometric properties (item difficulty and discrimination); (d) generate items by manipulating the task features to vary the cognitive complexity of the item-solving processes; (e) evaluate both the cognitive model (by using task features to predict performance in terms of response time and item difficulty) and psychometric model (by examining fit to the item response data) of the item generating system to establish construct representation and validity; (f) bank items by their sources of cognitive complexity; and (g) validate that the cognitive model provides a basis for specific hypotheses about the nomothetic span of the test. Referring back to the NRC Assessment Triangle, we can readily see the emphasis on the Cognition vertex in this approach; in fact, one can draw analogies between steps (a) and (b) above and Cognition, steps (c) and (d) and Observation, and steps (e) through (g) and Interpretation.

The CDS approach has been used for the design and development of mental rotation items and object assembly items (measuring spatial ability), progressive matrix items and non-verbal reasoning items (measuring abstract reasoning), and mathematical word problems (Embretson and Gorin, 2001, as cited in Ferrara et al., 2016). Examples include the Spatial Learning Ability Test (SLAT) developed by Embretson (1994), the Abstract Reasoning Test (ART) of the Armed Services Vocational Aptitude Battery (Embretson, 1998), and more recently, a new form for a test of fluid intelligence (ART-E1) used for the selection of law enforcement personnel (Embretson, 2016). The latest application of CDS is in the development of a computer-adaptive test for computational thinking that was administered to over 90,000 primary school students in the Netherlands (Hogenboom et al., 2021), which involved the creation of close to 4500 test items in an online game environment, and the validation of the cognitive model for the assessment.

Assessment engineering

Assessment Engineering (AE) is a “highly structured and formalized manufacturing-engineering process” to efficiently design and implement coherent cognitively based assessments (Luecht, 2013). According to Leucht (2012), the AE framework has several operational goals: “(1) to design and consistently measure the same intended construct(s) over time and conditions of measurement—for formative or summative purposes; (2) to fully or partially automate tedious, costly or time-consuming, human-dominant procedures; (3) to provide low-cost, scalable and efficient methods of producing a large number of items that may not have to be individually pretested, calibrated and then discarded after operational use (or re-purposed); and (4) to relax some of the pressure on data-hungry psychometric calibration and scaling models to do that “heavy-lifting” in establishing and maintaining one or more scale scores that measure the intended construct(s).”

Table 2 Procedural framework of the Cognitive Design System (CDS).

<i>Stage</i>
Specify general goals of measurement
Construct representation (meaning)
Nomothetic span (significance)
Identify design features in task domain
Task-general features (mode, format, conditions)
Task-specific features
Develop a cognitive model
Review theories
Select or develop model for psychometric domain
Revise model
Test model
Evaluate cognitive model for psychometric potential
Evaluate cognitive model plausibility on current test
Evaluate impact of complexity factors on psychometric properties
Anticipate properties of new test
Specify item distributions on cognitive complexity
Distribution of item complexity parameters
Distribution of item features
Generate items to fit specifications
Artificial intelligence?
Evaluate cognitive and psychometric properties for revised test domain
Estimate component latent trait model parameters
Evaluate plausibility of complexity factors on psychometric properties
Evaluate plausibility of the psychometric model
Calibrate final item parameters and ability distributions
Psychometric evaluation
Measuring processing abilities
Bank items by cognitive processing demands
Assemble test forms to represent specifications
Fixed content test
Adaptive test
Validation: strong program of hypothesis testing

Reproduced from Embretson (1998) with permission from the American Psychological Association.

To achieve those goals, AE makes “three fundamental assertions” (Leucht, 2012): (a) task content and complexity should increase across a proficiency or score scale to reflect the increasing level of knowledge and skill requirements along the scale; (b) a class or family of items can be designed from a model of task complexity that includes specification of the declarative knowledge (static representations of knowledge in memory) and procedural knowledge (cognitive skills), available tools, and overall complexity of the context or task setting required for items in the family; and (c) a large number of items with the same task complexity and statistical or psychometric properties can be generated within the same family using task templates and other quality control mechanisms.

There are four key stages in the AE process (Leucht, 2012, 2013): (a) construct mapping and evidence modeling; (b) task modeling; (c) template design and item writing; and (d) item calibration and quality control. These four stages can be seen as being analogous to the four building blocks in BAS (though each with its particular emphases), and hence share the same relationships with the NRC Assessment Triangle. Like the other principled approaches, AE begins with the fundamental design process of developing a construct map, which articulates the ordered proficiency-related claims on respondents’ knowledge and skills (akin to achievement- or performance-level descriptors) along an intended score scale. An evidence model is also developed alongside the construct map to describe the expected performance at each level of the scale, and this could include exemplars of work products or other performance-based evidence that support the knowledge and skills required by each proficiency claim.

In the next stage, a task model is created to provide detailed specifications for a class or family of items that share the same cognitive demands as well as other task features such as content, context, and auxiliary resources or tools. These specifications can be represented in a task model using a task model grammar, which allows items generated for the same family to be isomorphic in terms of cognitive complexity. With the specifications, each task model can be located on a specific region of the measurement scale by relating the task model’s cognitive complexity to the proficiency claims and associated evidence models. Each task model also provides the basis and efficiency for the building of assessment task templates, and the subsequent generation of items from each template. A task model map, as illustrated in Fig. 8, can then be created by arranging the task models along the scale to provide a visualization of the distribution of task models at different locations. The task model map is a formal design specification for the intended scale, and we would expect locations that require greater precision or richer interpretations to have a higher density of task models.

Fig. 8 Linking templates and items to the task model map and construct map in the Assessment Engineering (AE). Reproduced from [Luecht \(2012\)](#) with permission from Taylor & Francis Group LLC.

During the next stage of designing templates and item writing, the task model is implemented through template and item development. In particular, templates are created to maintain the interpretation of the knowledge and skills specified by a particular task model, and items are created as part of a family based on a particular template. Given that each task model has an implicit or ordered location, the corresponding templates and items would also need to adhere to that location or ordering. To facilitate that, each template includes three components that specify the presentation format, manipulable content, and scoring rules, namely, (a) the rendering model (also called item shell or item model) which sets the item type format and look-and-feel of the item; (b) the scoring evaluator which determines which response or other data is collected and used; and (c) the data model which contains all relevant data for presenting and scoring the item. The templates also form part of the quality control system, where quality assurance would require that items in the same template family behave similarly in terms of their psychometric and other characteristics. This leads to the final stage where the assessment tasks are field-tested and calibrated to validate the hypothesized complexity-proficiency ordering of items, templates, and task models.

AE is particularly helpful to the design and development of cognitively based assessments for both formative and summative uses. It also provides an efficient and cost-effective way to generate large numbers of isomorphic items for an item bank. A study by [Gierl et al. \(2008\)](#), for instance, has demonstrated that over 330,000 unique items could be generated from 10 mathematics item templates using an automatic item generator software.³ [Luecht \(2012\)](#) has further suggested that AE may be most beneficial for formative and diagnostic assessments, given that educators need to have a test which can produce profiles of student performance on a regular basis as part of the learning process. One related application is the College Board's Preliminary SAT/National Merit Scholarship Qualifying Test (PSAT/NMSQ), where the AE approach is used to generate and evaluate over 10,300 items based on 15 item templates ([Lai et al., 2010](#), as cited in [Ferrara et al., 2016](#)).

Principled design for efficacy

The Principled Design for Efficacy (PDE) is a "practical way to implement principled assessment design and development" by "helping test designers to make design decisions thoughtfully, explicitly, and systematically" ([Nichols et al., 2015](#)). Notably, PDE shares some similarities with other principled approaches, particularly ECD, such as being construct-centered and the documentation of validity arguments, and hence, it also shares ECD's relationships with the NRC Assessment Triangle. However, some features are unique to PDE. For example, PDE aims to make the assessment development process more efficient and effective by: (a) using knowledge, skills, and abilities (KSA) research from the human resources domain to inform test design and development; (b) emphasizing communication with various stakeholders; (c) working within internal and external constraints; and (d) considering the intended interpretations and uses of the test scores. Note that there has been some controversy about using KSAs in this way—see [Kay \(2011\)](#).

The PDE approach is driven by a conceptual framework with six inter-related design concepts (as illustrated in [Fig. 9](#)): (a) construct, (b) consequences, (c) content, (d) evidence, (e) communication, and (f) implementation. Not only does the conceptual framework guide the test development process, but it also provides a common language to facilitate reasoning and communication among different stakeholders of the assessment program. First, the concept of construct is associated with the question "What are you assessing?", which is answered by a description of the KSAs that inferences will be made about test-takers, and a validity framework documenting the chain of reasoning that links the intended interpretation and use of the test results to the test scores. Second, the concept of consequences is associated with the questions "What do you expect to happen when you assess?" and "What are the general processes through which the identified consequences are expected to occur?" and can be addressed by

³The reader is directed to the "Automatic Item Generation" article by Mark Gierl in this volume.

Fig. 9 Conceptual framework for the Principled Design for Efficacy (PDE). Reproduced from [Nichols \(2021\)](#) with permission from Planful Learning and Assessment LLC.

a theory of action that describes the process of change or mechanisms assumed to lead to the intended outcomes of the assessment. Third, the concept of content is associated with the question “How do you assess it?” and is concerned with how task content features can be manipulated to elicit the target KSAs, and to vary the task demand and complexity. Fourth, the concept of evidence is associated with the question “How do you know what you are assessing when you see it?”, which corresponds to specific instructions for interpreting test-takers’ responses, comprising work product specifications (what performances will be captured), evidence rules (how performances will be coded), and the statistical model (how coded responses will be aggregated to make inferences). Fifth, the concept of communication is associated with the question “How do you talk to people about what you are assessing?” and focuses on effective communication with different stakeholders (sponsors, content developers, test-takers, information users), who may bring different values and perspectives to the assessment program. Finally, the concept of implementation is associated with the question “How do you want to carry out the assessment program?”—this is about the thoughtful consideration of the assessment goals and purpose, needs of stakeholders and use of test results, test requirements and constraints, and context of administration in the design, development, and delivery of the assessment.

PDE is operationalized through four key stages of design and development activities: (a) construct definition, (b) content creation, (c) feature generalization, and (d) content re-creation. During construct definition, the assessment designer uses the research literature to define the content standards in terms of cognitive processes, knowledge structures, strategies, and mental models, and to articulate the general content features of stimuli and items that will elicit the explicated KSAs. This is followed by content creation where stimuli, items, and rubrics are developed from those general content features to capture the full range of performance in the target KSAs. Next, in feature generalization, more detailed guidelines and specifications are written for those stimuli and items created. Lastly, content developers use those guidelines and specifications to efficiently generate more stimuli and items during content re-creation. It should also be noted that the design concepts cut across the various stages of design and development. For example, the concept of communication is addressed throughout all stages of activities to achieve a shared understanding of the assessment (e.g. assessment goals, KSAs, content features) among stakeholders.

As seen above, PDE focuses specifically on the development of the test content instead of the entire assessment development process, and thus benefits from the application of learning sciences research. Further, the element of implementing the design and development process within practical constraints means that PDE can be used for existing assessments or new assessments that already have certain design decisions established. These two features support the intent of PDE as an enhancement rather than a replacement for current assessment practices ([Ferrara et al., 2016](#)). Thus, the PDE approach has mainly been used for educational achievement tests, especially in state-wide assessment programs such as the elementary and middle school formative assessment program for the Baltimore County Public Schools, and the NGSS assessment program in Maryland ([Ferrara et al., 2016](#)). Notwithstanding that, PDE has also been applied to performance tests, particularly embedded assessments in simulation-based and learning games—for example, the Insight Learning System, which is an integrated learning system for the teaching and

Fig. 10 The CIA triangle (top) and Black’s “vicious triangle” (bottom).

assessment of geometry (length and area) for Grades K-4 students; and the Common Core Speaking and Listening (CCSL) formative assessment system, which incorporates learning and feedback through simulation of real presentational speaking and two-way communication (DiCerbo et al., 2017).

Going “outside the triangle”

There is no more hackneyed phrase these days than “Going outside the box,” but indeed that is what we need to consider in surveying the relations of PAD approaches to the rest of the educational enterprise (though we have a triangle rather than a box!). We can see assessment as playing a key role in education, as is represented in the traditional “CIA Triangle”—Curriculum, Instruction, and Assessment—as shown in the top part of Fig. 10. The conceptualization in this diagram is that the aims of the educational activity are specified in the curriculum, then the method of delivery is embodied in the instruction (or, for those in the UK, the pedagogy), and then the evaluation of the activity is carried out via the assessments. However, Paul Black, from King’s College, London, has suggested a modification of this figure to illustrate what he sees as the deleterious effects of assessment on education. This, which he labels as the “vicious triangle” (Black et al., 2011), is illustrated in the bottom part of Fig. 10.

In this situation, the teachers’ instructional plans and efforts are “squeezed” between the overarching goals of the curriculum, and the concentrating and winnowing effects of external (often large-scale) tests which have been designed to hold teachers and schools to certain accountability targets. According to Wilson (2018):

The central issue is that the assessments (both classroom and large-scale) need to be working coherently with the curriculum. When that coherence breaks down, or as is sometimes the case, it was never there in the first place, the sorts of negative outcomes mentioned in the previous section can be expected to occur (pp. 7–8).

Black and his colleagues have suggested that what we require to avoid this dilemma is to build curriculum, instruction, and assessment on unifying theories of learning and teaching that assemble these three elements into a coherent educational process (Black et al., 2011). This is illustrated in the “Revised CIA Triangle” shown in Fig. 11, which symbolizes both the presence of additional forms of feedback among the three parts of the CIA Triangle, as well as the need for principles of coherence in the shape of theories of learning.

The reason that this account is relevant to the PAD approaches is that the part of this diagram related to assessment is very much what is the focus of PAD itself. That is, we must create structures for understanding and expressing the architecture of *both* curriculum and assessments together so that (a) the curriculum can be used to define the goals of the assessment (i.e. constructs to be assessed), and (b) the results of the assessments can be interpreted directly in terms of those curriculum constructs. What the Revised CIA Triangle adds in here is the element of instruction, which, of course, is the motor of the educational enterprise.

Fig. 11 The revised CIA triangle.

Thinking along these lines leads one to consider a theory of action concerning the implementation of the PAD approaches. This is ground that has already been trodden by another researcher and his colleagues (Bennett, 2010)—in this ground-breaking effort, researchers at ETS have endorsed a PAD-like approach but then gone beyond it (i.e. “outside the Triangle”), and considered not just the usual usages of assessment *of* learning, but also assessment *for*, and *as* learning—the Cognitively Based Assessment of, for, and as Learning or CBAL (see <https://www.ets.org/cbal>). More specifically, they are working to develop assessments in which (a) the activities of learning integrate assessments and their products (student outcomes and ways to interpret them), and (b) the activity of taking the assessments can itself act as a learning activity. The latter, of course, breaks with one of the usual assumptions about measurement, that is, measurement is based on indicators of student abilities, but the process of measurement does not, in itself, bring about changes in those same student abilities—modeling this phenomenon is a considerable challenge for modern psychometrics. See, for example, Mari et al. (2021), where this is discussed under the heading of “measurement that involves feedback” (pp. 227–228). The CBAL effort is an important initiative to take the advantages of the PAD approach, as discussed above, into the real world of testing.

Another related formulation for going outside the Triangle is designed to link into the current expansion of web-based learning technologies: *Expanded Evidence-Centered Design* (e-ECD; Arieli-Attali et al., 2019) extends the ECD framework to the design and development of technology-enhanced learning and assessment systems by adding specifications for describing aspects of learning associated with each of the three core models in the original ECD formulation. This enables a close detailing of the linkage and coordination between learning and assessment, through parallel layers or models, in the design framework. Importantly, this framework is written to a generic version of a learning theory, so that it can be used with a variety of learning systems.

Conclusion

One of the common complaints among the society of those who make their professional life in and around the creation and usage of assessments in education is that many lay-persons, and even professionals in education, such as teachers, do not see anything in an assessment instrument beyond the explicit set of items that constitutes the “test.” This is in marked contrast to the common thread among all of the PAD approaches described above—a determination that (a) the target variable underlying the assessment should be well-specified, and (b) there is a strong argument for the validity of inference from the assessment outcomes to that target variable. The items, though necessary of course, are seen in this light as ephemera—what was needed to provoke the interesting information.

Considering this, one of us has argued in the past (perhaps somewhat tersely) that “The instrument [i.e. the test], then, is seen as a logical argument that the results can be interpreted to help make a decision as the measurer intended them to be” (Wilson, 2004). This embodiment of the PAD argument in the form of the instrument acknowledges the crucial importance of the linkage between (a) and (b) in the previous paragraph that is supplied by the instrument itself. In this view, the test must be seen as being like an iceberg, with hidden (to the examinee) underpinnings in the shape of the relevant PAD components—for example, for BAS, the hidden parts are the construct map, the items design, the outcome space, the measurement model, the validity and reliability evidence, and the interpretative materials. One way to see the efforts we have described above to come up with PAD approaches is as a struggle to both understand what the basis is for using an assessment, but also to find a way to communicate this basis to the many types of assessment users, from students and teachers to policy-makers. For example, although professional standards (such as the “Testing Standards”) have an important role in maintaining quality assessment, it is only through the broad appreciation of what makes for a good assessment among the stakeholders (i.e. from students and teachers to policymakers) that there will be a continuing stream of support for the costly business of developing and utilizing sound assessments.

Introduction

Grounded in the concept of assessment as evidentiary argument, Evidence-centered Design (ECD) is a comprehensive framework for articulating the conceptual, inferential, and computational elements of educational assessment and explicating the interrelationships among substantive arguments, assessment designs, and operational processes. Within and across domains and contexts, assessments are intended to support inferences regarding learners' knowledge, skills, and abilities (KSAs), based upon observations of what they say, do, or make in a handful of situations (Mislevy et al., 2003). In ECD assessment is conceptualized as five coordinated layers of components, processes, and representations. Relating directly to test development are the Domain Modeling layer, which delineates the assessment design and use argument, and the Conceptual Assessment Framework (CAF), which instantiates the argument with specifics such as scoring methods, measurement models, and schemas for tasks. This article describes the basic ideas of ECD and illustrates and discusses its applications and extensions across domains. For further discussion of ECD, see the "Further Reading" list at the end of the article.

Assessment as evidentiary argument

The most fundamental consideration in test development and evaluation is validity, which refers to "the degree to which evidence and theory support the interpretation of test scores for proposed uses of tests" (AERA/APA/NCME, 2014, p. 11). Validity research thus concerns ways in which we can construct and use assessments to support interpretation and uses of test scores (Bachman and Palmer, 2010; Kane, 2006, 2013; Messick, 1994). Building an assessment argument means specifying elements that concord with Toulmin's (1958) argument schema. As is shown in Fig. 1 (Mislevy, 2018), the schema consists of a *claim* (C), which is a proposition we wish to support with *data* (D), and a *warrant* (W), which is a generalization that justifies the inference from the particular *data*

Fig. 1 Toulmin's general structure for arguments. The letters are the abbreviations for the following terms: B for *Backing*, D for *Data*, R for *Rebuttal*, W for *Warrant*, A for *Alternative Explanations*, and C for *Claims*.

(D) to the particular *claim* (C). When using the test, we reason back up through the *warrant* (W) from the observations to particular *claims* (C). Usually we must qualify our inferences because of *alternative explanations* (A), which *rebuttal data* (R) might support or undercut.

Assessment design means defining the kinds of claims we wish to make, and then crafting the operational elements of an assessment that allow us to reason in this manner. Messick (1994) outlines the essential structure:

A construct-centered approach would begin by asking what complex of knowledge, skills, or other attributes should be assessed, presumably because they are tied to explicit or implicit objectives of instruction or are otherwise valued by society. Next, what behaviors or performances should reveal those constructs, and what tasks or situation should elicit those behaviors? Thus, the nature of the construct guides the selection or construction of relevant tasks as well as the rational development of construct-based scoring criteria and rubrics (p. 17).

Test specifications

A traditional and useful representational form in the development of a test, regardless of its nature and intended uses, is the test specifications. The original focus was content and item types. Considerations of cognition were incorporated as in Bloom's (1956) taxonomy. Continued extensions provide additional support for the many specific considerations a test developer must make. Broadly-defined, test specifications document the test's purpose and intended uses while also including detailed decisions regarding its content, format, length, psychometric properties, delivery mode, administration, scoring, and score reporting (AERA/APA/NCME, 2014). From an ECD perspective, test specifications express selected information developed in the Domain Analysis, Domain Modeling, and CAF layers described in **Layers in ECD** section, in a form that supports the crafting of individual tasks and the composition of the test as a whole.

Assessment engineering

Another line of contributing research is assessment engineering and developing tools for improving the efficiency and quality of task design. Early theory-based approaches to task development were Hively et al. (1968) item shells, Haladyna and Shindoll's (1989) item forms, and Bormuth's (1970) transformational grammar item generation algorithms. Embretson (1985) provided a path toward integrating test theory, task design, and cognitive psychology. Irvine and Kyllonen (2002) reviewed articles and illustrative examples of theory-based item generation through 2000. More recent work varies physical features of tasks considered important cognitively (e.g., Gierl et al., 2008). Embretson's (1998) cognitive assessment design system and Luecht's (2013) integrated test design, development and delivery approach are two examples of technology supports for principled task design. From an ECD perspective, each of these efforts inform the development and the principled implementation of assessment tasks from a guiding construct, with results expressed in Domain Analysis and/or CAF objects.

Layers in ECD

ECD is best understood through its representation of layers in the design and implementation of educational assessment (Mislevy et al., 2002, 2003). Layering facilitates intrafield investigations as well as providing structures that support communication across realms of expertise (Riconscente et al., 2015). Table 1 summarizes the roles and key entities of layers, which are discussed below using examples and applications of ECD.

Table 1 Summary of ECD layers.

Layer	Role	Key entities	Examples of knowledge representations
Domain analysis	Gather substantive information about what is to be assessed.	Concepts, terminology, tools and representation forms; analysis of information use.	Representation forms and symbol systems employed in a given domain; common core state standards; state curriculum standards; syllabi.
Domain modeling	Express assessment argument in narrative form.	Knowledge, skills, and capabilities; task features; potential observations.	Toulmin diagrams; design patterns; claims, evidence, and task worksheets.
Conceptual assessment framework	Express assessment argument in specifications for tasks, measurement models, scoring procedures.	Student, evidence, and task model; task model variables; rubrics; measurement models; test specifications.	Task shells; task templates; graphical representation of measurement models.
Assessment implementation	Implement assessment, including creating tasks and fitting measurement models.	Task materials; pretest data for item and task scoring.	Items and tasks; design of test materials and score reports; item parameter data files.
Assessment delivery	Coordinate interaction of students and tasks; task and test-level scoring and reporting.	Task as presented; responses as collected; scores as evaluated.	Rendering of test materials; individual and group-level reports; data files of responses or logs of students' actions.

Adapted from Riconscente et al. (2015).

Domain analysis

Domain analysis marshals substantive information that has implications for assessment in the target domain. It is a preliminary synthesis of concepts, terminology, tools and representational forms that people engage with. While not constructed or organized in terms of the structures of an assessment, most of this information lays the foundation for developing it (Mislevy et al., 2002, 2003; Riconscente et al., 2015). Examples of this are beliefs, theory and research, subject-matter expertise, and exemplars from other assessments. Outcomes of this analysis include identification of KSAs that are essential for success in the domain, task features, and competency-task relationships. The design team for the Test of English for International Communication (TOEIC) speaking and writing test, for instance, initiated task design analysis by reviewing the framework papers for a related test, Test of English as a Foreign Language (TOEFL), in addition to the other materials about design and research regarding workplace and general English tests, which provided them with ideas about potential test tasks for the subsequent steps (Hines, 2010).

The inferences we wish to draw and the psychological perspective we take on the nature of KSAs serve as the starting point for domain analysis: our conception of the nature of human capabilities shapes the design and interpretation of elements, relationships, and rationale in an assessment argument. Four perspectives on construing instruction and assessment are trait, behavioral, information-processing, and sociocognitive, which holds implications for designing and using assessment (Mislevy, 2018). A trait is defined as a relatively stable characteristic of a person, consistently manifested to some degree, albeit with considerable variations across settings and circumstances (Messick, 1989). A prototypical example of tests cast in this perspective are aptitude tests, locating people along continua of mental characteristics, and supporting inferences regarding the degree to which individuals possess the capabilities. The domain analysis for these tests is thus an analysis of assemblies of abilities that capture individual between-person differences in the aptitude of interest. A behavioral perspective foregrounds targeted behavior in relevant situations, while placing cognitive and social considerations in the background. The domain analysis for tests cast in this perspective concerns features of what people do and features of situations in which the relevant behaviors are elicited. An information-processing perspective examines the procedures and cognitive processes individuals engage with for problem-solving. Assessment from this perspective focuses on the production system, i.e., knowledge, procedures, and strategies for problem-solving, in the domain of interest. An example of this is mixed-number subtraction, which provides diagnostic information regarding the strategies students use to solve the problems. From a sociocognitive perspective, people's thinking, acting, and learning in the physical world are mediated by "socially constructed practices, built around linguistic, cultural, and substantive (LCS) patterns and representations" (Mislevy, 2018, p. 47). From this perspective, individuals' capabilities are viewed as resource deployment and activation of cognitive resources attuned to LCS patterns that characterize regularities and variations in people and situations.

Domain modeling

The Domain Modeling layer articulates the assessment argument. It does not address technical details such as measurement models or data formats, but rather ways to fill in an argument scheme using information identified in the domain analysis layer. Schematic tools for this purpose are proficiency-, evidence-, and task paradigms, Toulmin diagrams, and design patterns. The paradigms are non-technical sketches of the student-, evidence-, and task models discussed in the ensuing section: proficiency paradigm organizes potential claims about students; evidence paradigm are the kinds of things students say or do that constitute evidence; and task paradigm are the kinds of situations that can be configured to obtain the evidence (Mislevy et al., 2003).

Fig. 2 is an extended Toulmin Diagram in the context of portfolio-based assessment of student interns pursuing K-12 teaching certification. The claim is an aspect of a student intern's KSAs for teaching a particular content area in K-12 classrooms. The evidence is an assembly of artifacts that reflect the student intern's teaching preparation and teaching practices in the assessment situations. In this assessment, student intern A is placed in a months-long internship program and has completed a number of teaching assignments for inclusion in the teaching portfolio, all requiring an integration of knowledge of a particular content area, of national and state teaching standards, and of unit- and content-based formative and summative assessment of student learning with teaching and assessment practices, which the student intern then demonstrates through completing tasks that include and are not limited to lesson planning, lesson delivery, and implementing unit-based formative and summative assessment. Theory and research regarding teaching and learning in that particular content area and national and state teaching standards provide backing in the assessment argument. A sociocognitive perspective sees the student acting in a given situation and frames claims, tasks, and evidence in terms of the student's regularities and variations for acting across situations, all informed by and contingent upon across-person regularities and variation at many levels of LCS patterns associated with the situations, and other information concerning the interaction between the student and the assessment situations (Mislevy, 2018).

Design patterns organize information from *domain analysis* to define a design space and an assessment structure for a task designer who needs to write tasks addressing the capabilities at issue (Mislevy et al., 2003; Riconscente et al., 2015). Table 2 shows the attributes of a design pattern. Focal KSAs are the capabilities which the tasks will be constructed to assess (i.e., the claims). Characteristic features of tasks must be included in some form in order to evoke evidence of the targeted capabilities, and variable features are ways a designer can shift focus or difficulty. Potential Work Products are the kinds of things student can say, do, or make to produce evidence, and Potential Observations are the qualities of the work that constitute evidence (e.g., accuracy of the inferences in a reading assessment).

Fig. 2 Extended Toulmin diagram in the context of portfolio-based assessment of student interns.

Table 2 Design pattern attributes and relationships to assessment argument.

Attribute	Description	Assessment argument component
Rationale	Provide a rationale for linkage between potential observations and focal knowledge, skills and abilities (KSAs).	Warrant
Focal knowledge, skills and abilities (focal KSAs)	The primary knowledge/skill/abilities targeted by this design pattern.	Student model
Additional knowledge, skills and abilities	Other knowledge/skills/abilities that may be required by tasks generated under this design pattern.	Student model, if construct relevant; alternative explanations, if construct irrelevant.
Characteristic features of tasks	Aspects of assessment situations that must be present in the task situation in order to evoke the desired evidence.	Task model
Variable features of tasks	Aspects of assessment situations that can be varied in order to shift difficulty or focus.	Task model
Potential observations	Characteristics of performance that constitute evidence about KSAs (e.g., accuracy, efficiency, correct inference).	Evidence model
Potential work products	Performances by which students can produce evidence about focal KSAs (e.g., written text, response choice, oral speech).	Task model

Conceptual assessment framework

The *conceptual assessment framework* (CAF) provides a structure for coordinating the substantive, statistical, and operational aspects of an assessment. The technical detail required for implementing the assessment is laid out in this layer. This layer specifies the operational elements of assessment machinery in the form of three models that instantiate the assessment argument. The Student Model operationalizes claims in terms of student variables, which can be as simple as an overall score, or as complex as the person variables in an item response theory or cognitive diagnostic model. Values assigned to student model variables, based on observing performances, correspond to claims about students' capabilities.

The Evidence Model contains two components, the *evaluation component* and the *measurement model*. The *evaluation component* contains procedures for identifying and characterizing salient features of examinee performances—that is, how to score task performances. Through evaluation procedures using answer keys, rating rubrics with examples, and so on, we determine the values of *Observable Variables* from students' Work Products. What aspects of student work are important and how to evaluate them are governed by the psychological perspective in which the assessment is framed. Tests cast in behaviorist terms, with its focus on stimulus-response bonds, may focus on qualities such as accuracy of the responses. Tests cast in sociocognitive terms highlight the appropriateness and effectiveness of the choices an examinee makes in the assessment situation. In interactive tasks, evaluation may draw on natural language processing methods, learning analytics, or data mining techniques, and may comprise multiple stages (as in the automated scoring of spoken responses; Higgins et al., 2011). The *measurement model* provides a mechanism for synthesizing such data across tasks or interactions and for quantifying the strength of evidence for claims, such as reliability coefficients and standard errors of measurement. Psychometric models such as classical test theory, item response theory (Wilson, 2005), and cognitive diagnostic models (Rupp et al., 2010) are used in this step.

The Task Model consists of blueprints for assessment tasks and work products. In applications using design patterns, task models reflect choices from the suggested range of Potential Work Products, and Characteristic and Variable Features and Potential Observations of the Work Products. This layer specifies work products and narrows down to central and optional task features that evoke evidence about the targeted claims. For example, performance-based assessment of student teachers will necessarily involve observations of a student teaching a content class, and evaluations of qualities of lesson planning and lesson delivery. In contrast, if the claim concerns mastery of content or pedagogical knowledge, a computer-delivered knowledge assessment in the form of multiple-choice questions or short-essay questions may serve the purpose. In assessments consisting of multiple discrete tasks, constellations of tasks are brought together as an assessment in the *assembly model* to determine the breadth and depth of the domain being assessed. Test specifications and blueprints are generated in this model on the basis of CAF models. In interactive tasks such as in simulations and games, specifications for how interactions between test-takers and the task environment are effected, data are captured, and evaluations are produced are specified in more complex forms of these basic ECD models (Conrad et al., 2014; Ke et al., 2019).

The implementation and delivery layers

The *assessment implementation* layer includes activities such as developing interfaces, authoring tasks, fine-tuning rubrics and examples, programming automated scoring routines, and fitting measurement models. It is in this layer that assessment-engineering developments in technology for creating elements such as adaptive testing, interaction in simulation environments, and capture and evaluation of complex performances are effected, based upon specifications laid out in the CAF. Behrens et al. (2012), for instance, provide worked-through examples of how Cisco Networking Academies designed its next generation automated performance-based assessment, the Packet Tracer system, using the ECD framework.

The *assessment delivery* layer includes processes for selecting and administering test items, interacting with examinees, reporting scores, and providing feedback to appropriate parties. The information, structure, and rationale of these processes embody the assessment argument laid out in domain analysis, are structured by the blueprint laid out in the CAF, and utilize the operational elements created in *Assessment Implementation*. Details of delivery system architecture are provided in Almond et al. (2002) and, as extended to interactive digit assessments, in Conrad et al. (2014).

Applications and extensions

Across domains ECD applications involve its principles in action for developing large-scale assessment, for revising existing tests to more coherently articulate the assessment argument and align learning and assessment, and for generating simulation- and game-based assessment (GBA). The procedures Educational Testing Service used to develop test blueprints for the TOEFL iBT illustrates ECD principles as applied to a large-scale assessment of English learners (ELs) (Chapelle et al., 2008). Defining the construct to be measured and claims and subclaims about examinee abilities constitutes the proficiency paradigm in the domain modeling layer. For example, a claim for the speaking test is defined as "[examinees] can communicate effectively by speaking in English-speaking environments" (Pearlman, 2008: 232). Subsequent steps characterize observations for grounding them and identifying real-world tasks to provide evidence, resulting in evidence paradigms and task paradigms in the same layer. Based upon these results, templates for generating items or tasks, tasks shells, are constructed to incorporate essential elements of tasks models in the conceptual assessment framework (e.g., Pearlman, 2008: 237–238).

The redesign of Advanced Placement (AP) examinations is an illustration of the use of ECD for revising the existing suite of AP exams designed to measure skills and knowledge essential for success in introductory-level college courses (College Board, n.d.). Parallel to the redesign of the AP curriculum which begins with clearly defined learning outcomes essential for success in subsequent college courses, revision of the AP exams using the ECD approach begins by asking what kinds of claims we want to make about the students for the purpose of predicting their success in subsequent college courses, what kinds of evidence can support these claims, and what assessment tasks can provide evidence of the claims. The Domain Modeling layer focuses on developing exemplar claims and supporting evidence that characterize student performance at each of the achievement levels, i.e., Achievement Level Descriptors (ALDs), which are then used to construct the assessment framework (Brennan, 2010). Task models are embedded within each achievement model, which becomes the basis for generating items and test specifications. The use of ECD in redesigning AP exams explicitly articulates an evidentiary argument to support score interpretations as well as provides direct linkage among claims, evidence, task models, items, achievement levels, and test specifications (Hendrickson et al., 2010).

In the emerging field of GBA, an integration of ECD into the game development process leverages game design principles and mechanics to generate engagement, and assessment design principles and methods to generate useful evidence pertaining student learners' understandings and capabilities (Mislevy et al., 2014). An example of this is the GlassLab's game SimCityEDU: Pollution Challenge! which addresses the concept of "Systems and Systems Modeling" in the Next Generation Science Standards. The domain modeling layer draws on theory and research regarding the developmental trajectory of students' scientific reasoning and system thinking to gather substantive information about the assessment and assessment situations. Built upon this, an assessment design team consisting of game designers, psychometricians, subject-matter experts, teachers, psychologists, and experts in other relevant areas, each using their own language and tools, sketched out the essential elements of an assessment argument using the Toulmin Diagram and design patterns for each of the developmental levels in system thinking, while simultaneously addressing competing constraints. These elements translate into specifications of the student-, task-, and evidence models in the CAF, which define the operational elements subsequently constructed, prepared, and delivered in the assessment implementation and delivery layers.

Advances in computer technology and availability of rich data have brought forth myriad opportunities for assessment designers to apply and expand on ECD to develop innovative complex learning and assessment systems (e.g., Arieli-Attali et al., 2019; Behrens et al., 2012; Mislevy et al., 2012). One way assessment designers expand on ECD is to utilize rich data generated from simulation and game-based assessment to inform scoring rules and game design (Conrad et al., 2014; Grover et al., 2017; Shute et al., 2010). Adaptations also include retrofitting extensions to learning systems, or "ECD for Learning" (ECDL); Arieli-Attali et al. (2019) and Feng et al. (2009), for example, extend ECD with pedagogical models to utilize data within existing learning products. More generally, the expanded ECD framework (e-ECD; Arieli-Attali et al., 2019) expands all three basic models—for students, evidence, and tasks—by adding an additional learning layer in each model to specify targeted learning objectives, to provide task-based learning support, and to capture evidence for changes in learning. These point to important ways the ECD framework can coherently blend learning and assessment and simultaneously inform and guide learning in an era when the use of computer technology and digital devices has become ubiquitous.

Future directions

Scientific understanding of how students learn has advanced radically, and new technologies are coming online continually to provide interactive task environments and capture the resulting evidence. The challenge is harnessing this new knowledge for practical testing purposes—effectively, validly, affordably. Evidence-centered design provides a coherent conceptual framework that makes explicit the principles and interacting structures of argumentation, analysis, and operation that underlie assessment. It provides language and concepts to help developers design and coordinate the elements of familiar assessments as well as new ones. It motivates definitions of data structures and operational processes that can be used and re-used flexibly, across projects and organizations.

The work described in this article represents current practices in developing and using ECD. Future work will fill the framework out more fully, provide additional worked examples, and develop software tools and knowledge representations that make it easy for test developers to put the ideas to use. In the domain modeling layer, design patterns are needed to provide and support performance assessments and simulation-based assessments that focus on interactive capabilities. In the CAF layer, we need task design frameworks, adaptable modules for measurement models, and automated or rubric-based evaluation procedures, all explicated in terms of their relationship to assessment arguments. Recent work mentioned earlier shows how researchers are extending the ECD framework to incorporate learning with assessment and to detail the more complex design and analysis interplay in game- and simulation-based assessments. In the implementation and delivery layers, we need further representations and data structures that exploit computer capabilities to build, administer, and evaluate tests. These are ambitious and broad undertakings, spanning years or decades. At the same time, however, the most fundamental ideas of ECD—carefully thinking through what capabilities one wants to assess and the kinds of things we need to see learners do in what kinds of situations—can be put into action immediately by every teacher and every test designer in the field.

Introduction

Digital assessment tasks and technology-enhanced items provide many design palettes and choices for assessment developers that go far beyond the options available in paper-and-pencil assessments. The interactive affordances of digitally-based assessment have led to some dramatic changes to the front-end design and the test-taker experience, as well as the types of data collected. Test takers' interactive behaviors, together with system events, can be captured at the back-end of digital assessment environments. With continuous logging of events in this "process data", and with timings captured to millisecond precision, test creators and administrators can capture detailed information about the observable external processes that precede, co-occur with, and broadly correlate with test-taker responses.

As a consequence, digital tasks and items have the potential to gather more evidence than was previously possible for inferences about test-taker knowledge, skills, and abilities, and offer a wider range of design possibilities for targeting so-called "hard to measure" constructs (Bennett et al., 1990; Parshall and Brunner, 2017; Parshall and Cadle, 2014; Parshall et al., 2011; Sireci and Zenisky, 2011). In some cases, they can also support inferences about contextual information such as test-taker response or solution strategies, (dis)engagement, and metacognitive processes (e.g., Arslan et al., 2020; Eichmann et al., 2020; He et al., 2021; Wise, 2017).

Nonetheless, the use of digital tasks and items in educational assessment is not on its own guaranteed to improve the quality of the assessment results or the validity of the inferences made from the data gathered. Purposeful, cognition-centered design of both the front-end and the back-end of digital items and tasks is crucial for achieving these goals.

Goals and scope of this chapter

Although computerized assessments offer many exciting design options, a lack of evidentiary basis for design decisions can threaten the validity of the interpretation of test scores (Parshall and Brunner, 2017; Parshall and Cadle, 2014; Parshall et al., 2011). In order to capitalize effectively on the tremendous potential of digital assessments, we argue that it is important to apply an evidence-based, theoretically-grounded *cognitive* framework to support digital design decisions from a principled basis. Starting from a cognition-centered foundation can help to ensure that interactive digital tasks and items are: (a) designed in ways that are consistent with human cognition; and (b) designed to optimize the interactive affordances available for gathering process data as evidence of the non-visible cognitive processes occurring in the mind of the test taker. In addition, applying cognitive theory provides an evidence-based theoretical grounding for evaluating the potential strengths and drawbacks of using different task types and design features for particular goals. This in turn should help to support the overarching assessment goal of making valid inferences about test takers (Katz et al., 2017).

Applying a cognition-centered approach means drawing on insights and principles from the decades-long cognitive and learning sciences research literature to proactively inform task and item design. The approaches and principles we present in this chapter, drawn from this body of knowledge, are well-aligned with the goal of designing interactive items and tasks to elicit construct-relevant and valid evidence for target constructs in the form of both product (i.e., response) and process data, and should support the effective design of interactive digital assessment tasks of all kinds. Note that many of these principles were originally established in instructional design research with a focus on learning materials and have not yet been subject to systematic research in assessment contexts; therefore, further research is certainly required to better understand their effects in testing (see also [Kirschner et al., 2017](#); [Lindner, 2021](#)). Nonetheless, there is evolving evidence that these principles can be helpful for better design of assessment tasks and items.

Digitally-based assessment tasks range from technology-enhanced test items with various response formats, such as drag-and-drop, inline-choice, or grid (e.g., [Arslan et al., 2020](#); [Moon et al., 2019](#)), to interactive performance tasks, including simulations and games (see [DiCerbo, 2022](#), this volume, for a detailed review), and extended scenario-based tasks and microworlds (e.g., [Krieger et al., 2021](#); [Sheehan and O'Reilly, 2012](#); [Zhang et al., 2019](#)). There is no single agreed-upon classification system or naming protocol, nor are there absolute boundaries between different kinds of tasks and items (e.g., a simulation may be designed to be more or less game-like; extended “scenario-based tasks” are often created from sequences of related short items with multimedia content and interactive features). Digital assessments also typically include additional materials such as tutorials and instructions, universal design elements, and accessibility tools, as well as the assessment interface. Given this complex background, our goal is to describe digital task design principles that are broadly domain-agnostic and not restricted to a certain task type or only relevant to assessment in a particular discipline.

What we discuss below are cognitively-grounded, domain-agnostic design considerations, which we believe should be considered throughout the course of digital task design and development. These must be balanced and integrated with content-specific domain-expert knowledge and assessment development expertise in order to meet the specific needs for construct-validity in a given assessment. The primary use-case we consider is summative assessment (i.e., assessments *of* learning), but much of what we cover is also relevant to formative applications (i.e., assessments *for* learning, [Bennett, 2011](#); [Black and Wiliam, 2009](#)).

In the remainder of this chapter, we first review some common features of digital tasks and items (**Characteristics of digital assessment tasks and technology-enhanced items**). We then discuss cognitively-based principles to support the design of digital tasks to be consistent with human cognition and information processing constraints (**Principles for cognition-centered task and item design**). Following this, we discuss how to design interactive digital tasks to collect useful process data for making valid inferences about test takers (**Designing tasks for process data modeling, analysis, and reporting**). Finally, we provide take-home conclusions and future directions (**Conclusions and future directions for researchers and practitioners**).

Characteristics of digital assessment tasks and technology-enhanced items

Although there is no single universally-agreed set of characteristics for categorizing and defining digital assessment tasks, various authors have attempted to describe the range of resources that exist in digital assessments. One high-level distinction is whether the problem has a single definitive correct response. [Bull and McKenna \(2003\)](#) describe *objective testing* as tasks in which the correct answer is predetermined. These tasks tend to include recognizable assessment components such as a stem and a response field or a set of response options. They might also make use of some interactive digital design affordances to present information or to allow different kinds of response modes. Since the correct answers are predetermined, they have the potential to support automated feedback to test takers. Objective tests are well suited to testing factual knowledge, but they can also be creatively designed to assess more complex constructs at the higher end of Bloom’s taxonomy (e.g., analysis, synthesis, evaluation; [Bloom, 1956](#); see also [Anderson et al., 2001](#)), especially if interactive capabilities or multimedia elements are incorporated in a construct-relevant manner.

[Bull and McKenna \(2003\)](#) defined a second category comprising activities in which there is not a single predetermined “correct” way of responding. These open-ended activities tend to make full use of interactive digital capabilities such as simulations, interactive multimedia, computer-mediated communication, virtual environments, and complex technology-enhanced items for the evaluation (or acquisition) of complex skills and knowledge. They are also potentially harder to score. The distinction between objective testing and open-ended testing is similar to the long-established distinction in cognitive science between well-defined problems and ill-defined problems ([Lynch et al., 2009](#)). Although not a strict dichotomy ([Le et al., 2013](#)), there is nonetheless substantial evidence that different cognitive processes occur when tackling these two kinds of problems (see, e.g., [Dörner and Funke, 2017](#); [Schraw et al., 1995](#)), and therefore this is an important high-level task characteristic for assessment designers to consider.

Several authors have focused primarily on the interactive affordances of computerized tasks. [Parshall et al. \(2002\)](#) used the term *innovative item types* to refer to items that have features or functions available as a result of being administered on a digital device. They identify five dimensions of innovation in computer-based assessment: item format, response action, media inclusion, level of interactivity, and scoring method. They claim that innovative items can improve measurement by: (a) reducing guessing (e.g., increasing the degrees of freedom for options that can be chosen in selected responses, or having test takers produce new types of constructed responses); (b) measuring some knowledge or skill more directly than traditional item types (i.e., having response formats that better map onto the cognitive process or mental representation of the test taker, such as clicking directly on a section of a graphic, or dragging and dropping sources into targets to represent a sequence of events); (c) expanding the content coverage (e.g.,

by presenting information via audio or visual media); and (d) expanding the cognitive skills measured (i.e., by having test takers participate in activities that are only feasible through interactive digital technologies).

Scalise and Gifford (2006) also focused on the interactive affordances of technology-enhanced items. Their taxonomy organizes innovative item types into seven categories, arranged according to the degree of complexity and the constraints placed on test takers in terms of the available ways of interacting and responding, ranging from fully constrained responses—traditional multiple-choice items—to fully constructed responses—essay items (see also Bennett et al., 1990, for an earlier classification of constructed response items). Their taxonomy is applicable to all innovative item types, including formats that use simulations, multimedia, animations, audio, and/or video resources.

Scalise and Gifford (2006) also emphasize that more research is needed to ensure that the potential advantages of innovative item types do not exceed the risks of incorporating them into assessment or learning environments (see also Russell, 2016, for a framework regarding the utility of technology-enhanced items; Sireci and Zenisky, 2016, for a review of the implications of the use of innovative item formats on score validity; and Bryant, 2017, for a review of the potential advantages and limitations of technology-enhanced items). Areas of potential risk include the possibility of cognitive overload occurring in test takers, as well as the risk of test takers engaging in unintended and construct-irrelevant processes, resulting from the rich and potentially complex design options offered by digital tasks. In the next section, we highlight some domain-general principles for designing digital assessment tasks and items that take into account the limitations of human cognition and can help to reduce the risk of cognitive overload.

Principles for cognition-centered task and item design

The cognitive and learning sciences have well-established knowledge bases and have developed broadly applicable principles relevant to design, generated over many decades from extensive empirical research conducted in fields such as cognitive psychology, educational psychology, human factors, human-computer interaction, attention and perception, usability design, multimedia design, embodied cognition, and interactivity research. The constraints of human cognition apply regardless of whether a task is designed for paper-and-pencil or computerized administration. But digital assessments offer many more design possibilities and therefore understanding how their varied information types and formats will be processed, and how test takers will think and behave with their interactive affordances, is especially important. As in all human information processing, the processing of test material involves perceptual, attentional, cognitive, and action systems that are tightly interconnected and have known properties and constraints. Designing digital materials in ways that are consistent with human cognition can help test takers:

- attend to key information rather than task-irrelevant information,
- be less likely to experience overall sensory and cognitive overload,
- more easily integrate text, images, and other types of information, and
- expend less cognitive capacity on extraneous (irrelevant) processes.

In the next sections we highlight some key properties of human cognition and related design principles that we believe are especially relevant to digital assessment design.

Working memory and the constraints of human information processing

When digital assessment tasks or learning materials are presented, the information is perceived via sensory channels, filtered and selectively attended to, and a mental representation is formed. The mental representation is synthesized with preexisting long-term knowledge from prior experience, mentally manipulated, and continually refreshed and updated with newly-encountered external information. Working memory (WM) is the mind's online workspace where this moment-to-moment representation and processing of information occurs (Baddeley, 1986, 2003; Baddeley and Hitch, 1974).

WM has dedicated buffers for handling and translating between different kinds of information—a phonological loop for generating and processing verbal-auditory information (sometimes called the “inner voice” and “inner ear”), and a visuo-spatial buffer for generating and processing visual and spatial images (sometimes called the “inner scribe” and “inner eye”; Baddeley, 1986). For example, when we read, we initially perceive and encode the text in its visual form, but the words are converted into a phonological form (the inner voice) in WM, to allow sense-making and manipulation of the information. WM also supports complex cognition involving higher-level “executive functions,” such as synthesizing different types and sources of information, generating new mental representations, and allocating cognitive resources to different mental activities (Baddeley, 2003).

Although WM is highly flexible and invaluable for our ability to process and respond to incoming information, it is also a relatively fragile and limited-capacity system (Cowan, 2010). That is, WM can only hold a relatively small amount of information at any given time; the information in WM is easily disrupted, such as by new incoming information; and it takes conscious mental effort to maintain and manipulate information in WM—for example, think of the mental effort it takes to hold complex information in your mind and how that information can be instantly lost if someone unexpectedly asks you an unrelated question. Understanding the ways in which WM and human information processing can create a bottleneck, and how information overload can be ameliorated, is important for designers of digital materials.

First, even before information reaches WM, competition can occur between the incoming signals if they involve the same sensory channel—for example, if an animation is presented simultaneously with captions underneath, trying to attend to both is likely to cause split attention (Ayres and Sweller, 2005). By contrast, auditory narration uses a different sensory channel and therefore does not compete with the animation for the viewer’s visual attention (Mayer, 2008).

Second, the buffers that hold information in WM are capacity-limited and easily disrupted by new incoming information, such that interference may occur even when information is received through different sensory channels. For example, reading text (visual) while hearing unrelated speech (auditory) causes interference. Even though these signals enter WM through separate external sensory channels, both contain linguistic information that must be processed in the phonological loop, and therefore they compete for the limited capacity of this WM buffer (Baddeley, 1986; Baddeley and Hitch, 2019).

Further, the higher-level executive capacities of WM that allow us to engage in complex cognitive activities are also limited, so that multipart or very demanding complex tasks cause difficulty and detriment in task performance (e.g., see Borst et al., 2010). Thus, designers of digital assessments should think about both the *external* representations they are presenting and the *internal* or *mental* representations and processes that are expected to derive from and be required by the external information, when considering test-taker capacity-limits in relation to these different aspects of information processing.

Cognitive load

The term “cognitive load” is often used as informal shorthand for overall mental effort during an activity that calls for WM resources. In the literature, theories of cognitive load have been developed and many empirical studies have been conducted to examine the effects on learning and performance from different types and sources of cognitive load (e.g., Sweller et al., 2011; Wirzberger et al., 2020). Given the role of WM in consciously-controlled, cognitively effortful information processing, and given its known capacity limitations (Baddeley, 1986; Engle, 2002), cognitive load in complex tasks can also be thought of as primarily WM load, that is, the amount of mental work conducted in WM (e.g., see Sweller, 2020).

Researchers have characterized different types of cognitive load. The so-called “intrinsic load” (Sweller et al., 2011) or “essential processing” (Mayer and Fiorella, 2014) of a given task has been characterized as the inherent mental work or the necessary cognitive steps required to complete the task. However, it is also recognized that the amount of task-relevant load is actually a product of the interaction between the task characteristics and the knowledge, skills, and aptitudes of the individual working on the task (Kalyuga et al., 2003). For example, a mathematical equation may be solved rapidly and easily by a proficient student, for whom the problem triggers previously learned, automated solution procedures (i.e., schemas), thus reducing the amount of work that has to be done in WM (e.g., Kalyuga, 2009). By contrast, for a less proficient student who does not have these automated schemas, the same task may pose more demands on WM.

So-called “extraneous load” refers to the mental effort expended on activities that are irrelevant to or unnecessary for the task at hand. For example, unproductive effort may be required to process information from displays that are poorly designed (Paas et al., 2004; Saß et al., 2017). Thus, extraneous load is not inherent in the task itself but arises from the way information is presented. For example, the way a task is designed may cause additional effort to locate, comprehend, or integrate task-relevant information, such as having to switch between tabs or having to mentally integrate text and diagrams that are spatially or temporally separated in the display (e.g., see Moon et al., 2022). Consequently, extraneous load can be altered by adjusting the way a task is designed and how the information is presented (see also the related distinction between informational equivalence and computational equivalence; Simon, 1978).

Understanding these ideas should be helpful for designers of assessment materials when thinking about both the task itself and the way in which it is represented. A central goal of assessment is to achieve desired item difficulty while avoiding construct-irrelevant variance (i.e., “excess reliable variance that is irrelevant to the interpreted construct”; Messick, 1989). It is important for assessment developers to consider potential sources of extraneous load or construct-irrelevant difficulty arising from the way information is presented. It should also be remembered that, as stated above, test takers with relevant prior knowledge may be able to offload otherwise cognitively effortful WM processes onto automated schemas, and thus total WM load for those individuals should be lower regardless (Koedinger and Anderson, 1990).

Using cognitive theory to predict and explain when and why different kinds of cognitive load might arise in a given task can provide a theoretically-grounded framework to inform design choices and reduce construct-irrelevant variance. Below we outline some principles that have been developed to reduce undesirable and task-irrelevant sources of WM load.

Gestalt principles of visual perception

The Gestalt school of psychology, which emerged in the early 20th Century, gave rise to a set of universal laws describing the ways in which humans perceive the world (e.g., see Wagemans et al., 2012 for original and more recently added Gestalt principles of perception). Of particular relevance to task design are the Gestalt principles of grouping, which refer to visual characteristics that tend to make viewers perceive elements as belonging together. These phenomena can be co-opted in the design of visual displays to support the perception of relatedness among elements and help learners attend to and perceive, or make connections among, aspects of the information presented.

The principle of grouping (see Wagemans et al., 2012) states that elements in the display will be perceived as related or belonging together if they are visually similar, which can include similarity of color, size, shape, orientation, motion, timing, font, and

synchronized changes. For example, color-coding a key term in the text and using the same color to highlight part of an image signals to the viewer that these two aspects are related (i.e., that the color-coded term is the name of the depicted object; [Richter et al., 2016](#)). Elements will also be perceptually grouped by the viewer if they are located close to each other; if they are symmetrical or parallel to each other; if they appear to form a continuous entity or a complete closed figure; and if they are contained within the same region or area (e.g., objects that are located inside the same boundary or the same shaded region of a screen will be perceived as belonging together).

These principles can be used to “pre-organize” information on the screen to reduce extraneous effort spent searching for connections, or to guide test-takers to attend to information in the intended order. Grouping principles of various types can also be used to proactively signal meaningful connections between elements to help in building a mental representation of the information or the problem to be solved (e.g., see [Kirschner et al., 2017](#); [Moon et al., 2022](#); [Saß and Schütte, 2016](#); [Saß et al., 2017](#)).

Affordances

When someone sees an object for the first time, its appearance can provide clues about how to interact with it. For instance, the shape and construction of a chair affords the action of sitting, the handle on a cup is designed to be grasped. These design aspects of objects, which provide opportunities for acting on them ([Gibson, 1979](#)) and may even “invite” certain behaviors ([Norman, 1999](#)), are known as affordances. Affordances are therefore easily perceivable action possibilities in external objects ([Norman, 1988, 1999](#)).

Controlled experimental studies have shown that different affordances in the design or layout of technology-enhanced items that are otherwise content-equivalent can affect test taker behaviors, time on task, and/or performance. The effects observed in these studies include differential behaviors elicited when response options were formatted in a grid layout versus a multiple-choice list ([Moon et al., 2019, 2020](#)); performance and response strategy differences generated by drag-and-drop items designed with different layouts and interactive features ([Arslan et al., 2019, 2020](#)); impacts on problem-solving efficiency and time on task in items incorporating an interactive signaling tool and/or spatially integrated information ([Moon et al., 2022](#)).

Such findings indicate that the affordances of different item formats and designs, including technology-enhanced interactive components, are critical to consider because they affect test-taker behavior and cognition even when the content is identical. [Kirsh \(2005\)](#) argues that good design helps users “discover” the affordances of external representations in such a way that they can make effective use of them. Item designers should therefore carefully consider the affordances that result from different design decisions. It is also important that researchers continue to explore these effects in carefully controlled experimental studies grounded in cognitive theory and communicate the implications of their findings to practitioners working in digitally-based assessment design.

Interactivity

Closely related to the notion of affordances is the issue of interactivity. Interactive resources, where the user can control what is on the screen to varying degrees, have become commonplace in digital assessments. The types of interactions available can range from relatively constrained interactions involved in selecting and providing a response (e.g., drag-and-drop; see [Arslan et al., 2020](#)) to resources that provide almost limitless degrees of freedom, such as simulations, games, and virtual worlds (e.g., [Ke and Shute, 2015](#)). In the cognitive science literature, researchers have identified different types and degrees of interactivity, from low-level control over pace and direction (play, pause, rewind, etc.), to altering parameters or exploring information from different perspectives. Interactions with materials can range from sequential, hierarchical, or nested structures to fully conditional interactivity that is responsive to all user manipulations (for some discussions of different types, levels, and definitions of interactivity, see [Bétrancourt, 2005](#); [Domagk et al., 2010](#); [Kioussis, 2002](#); [McMillan, 2002](#); [Renkl and Atkinson, 2007](#)).

In terms of whether having interactive control is helpful for cognition, the results of previous studies are mixed. With different tasks, users, and types of interactivity, different studies have found advantages, no differences, and even disadvantages for participants with interactive control of resources, relative to those not given control (e.g., see [Keehner et al., 2008](#), for an overview). Drawing conclusions about the benefits of interactivity is complicated by the fact that studies differ in the comparability of interactive and non-interactive conditions and in the levels and types of control available. However, the literature to date suggests that providing an interactive resource for communicating key information does not guarantee that it will improve comprehension or performance.

The ability of a user to grasp how to use an interactive resource effectively probably depends on internal factors, such as previous experience and expertise, and on the affordances of the external information itself, such as what is represented (and how familiar it is to the user), the method of control, the range of interactive behaviors that are possible, and the complexity of the information. For example, in a review of the literature on interactive animations, [Bétrancourt \(2005\)](#) hypothesized that only certain types of individual (e.g., those with more experience) will benefit from certain types of interactivity. Designers of interactive tools should therefore consider how the features of their design might interact with the characteristics of the intended user. For example, if a tool is designed primarily for domain experts, different principles would apply compared to a representation designed for domain novices. Assessment designers should also aim to make sure (ideally confirmed with empirical evidence gathered from user studies) that the intended interactive affordances are easily discoverable and useable in the design of the task, interface, or tool ([Kirsh, 2005](#); [Norman, 1999](#)).

Multimedia

Multimedia representations are typically defined as resources that present information using both words and pictures (Mayer and Fiorella, 2021). Multimedia design principles (e.g., see Mayer, 2014; Mayer and Fiorella, 2021) are research-based guidelines for designing these kinds of instructional materials to be consistent with the capabilities and constraints of WM and its associated sensory and attentional processes. Designing educational materials in line with multimedia principles has been shown to have significant positive effects on information processing and learning outcomes (e.g., see Mayer and Moreno, 2003).

It should be noted that the multimedia design principles have been established and empirically investigated mainly in relation to learning goals. Given the differences between learning and testing in terms of both educational goals and educational settings, it is unclear to what extent multimedia principles can simply be transferred from learning to testing materials (see Lindner, 2021 for a discussion). Below we provide descriptive suggestions with potential implementation examples in the assessment context, but more research in the context of assessment design is needed to validate the principles and investigate their boundary conditions for this specific use case.

Nonetheless, assessment developers should still be aware of multimedia design principles and consider them in their design decisions, since these principles respect and account for the limits of human cognition, and their implementation will therefore most likely reduce unnecessary WM load in assessment materials as well. In Table 1, we present a summary of some key design principles (synthesized from Mayer, 2014; Mayer and Fiorella, 2014) that could be particularly relevant to item and task design in assessment materials.

Visual media

Visual representations are ubiquitous in education and also play an important role in assessment. Given their proliferation and the many different types of visual displays that are used, we devote an extended section to discussing different types of visual media, their uses in assessment, and what has been learned about their cognitive properties and effects.

Use of visual media in education and assessment

With digitally-based assessments, the choice of available visual formats spans both static resources (e.g., pictures, diagrams, graphs) and dynamic formats with varying degrees of user control and interactivity (e.g., playable animations, interactive simulations, user-controlled dynamic data visualizations). Educational content, especially in STEM subjects, is often focused on phenomena involving objects, processes, relationships, systems, quantities, and theories or models. Including representational pictures along with text (i.e., multiple representations) can help to make this kind of information clearer than text only, less potentially ambiguous, and easier to understand, by directly displaying aspects such as physical characteristics or relationships, rather than making students attempt to reconstruct these properties mentally from text-based descriptions alone (e.g., see Ainsworth, 2006).

There are several ways in which well-designed visual displays can augment cognition and offload some of the mental effort associated with WM processes (e.g., see Ainsworth, 2006; Hegarty, 2011; Mayer and Fiorella, 2021; Padilla et al., 2018; Schnotz and Bannert, 2003). These include offloading the effort of mentally maintaining information in WM by making it available for reference in the external display; organizing the information in ways that support processes such as filtering, attending, visual search and integration; and offloading the process of perceiving patterns or key information (e.g., plotting data in a line graph instead of a bar graph to reveal a trend). Nonetheless, interpretations of displays are impacted by prior knowledge of the task content, and success in understanding and using a display depends on attending to it, interacting with it effectively, and having knowledge of relevant design conventions (e.g., see Hegarty, 2011; Schnotz, 2005).

For different types of visual displays in a task, assessment designers should support and guide test-taker attention by adhering to the multimedia and Gestalt principles referenced above (Mayer, 2014; Wagemans et al., 2012), such as signaling meaningful connections between sections and organizing information to make synthesis and integration of elements easier (e.g., Moon et al., 2022; Richter et al., 2016). However, test designers always need to keep in mind that support for test takers' mental model construction must be aligned with the measurement of the target construct, which is an individual decision tied to a specific assessment goal (e.g., see Lindner et al., 2017a,b).

To support informed decisions for selecting, modifying, or designing visual displays for assessments, it is important to evaluate the type of representation in terms of its general cognitive properties and how it might impact test-taker cognition and behavior (e.g., see Lindner, 2021). Images can be distinguished in various ways in the context of assessments, mainly based on their informational content (i.e., decorative, representational, organizational, informational, see Hu et al., 2021; Lindner, 2021, for classifications) and their relation to the explanation that is given in accompanying text. In the following subsections, we discuss in more detail some commonly used types of visual representations and their effects in assessment.

Representational and decorative pictures

Static pictures are frequently added to assessment tasks, but it is important to distinguish between different types of pictures and their functions. In assessment research, *representational pictures* can be defined as images that represent information from a corresponding text item stem in a pictorial way, without adding novel task-critical information (Lindner, 2021). Representational pictures are frequently used to display task- or construct-relevant information that is integral to the cognitive processes targeted

Table 1 Summary of instructional design principles that may be relevant for item and task design in assessment contexts, assuming the supported cognitive process is **not** part of the target construct of the measurement.

Principle or finding	Core idea	Potential implications for test item design	Example references for further information
Multimedia principle	The presentation of text with relevant pictures is more effective for learning than presenting text alone (i.e., better exploitation of WM capacity of the visual and verbal channel) and facilitates a proper mental model construction (e.g., by constraining interpretations).	Consider presenting task-relevant text information together with a corresponding representational or organizational picture to facilitate test-takers' mental model construction and understanding of a situation, if this is a prerequisite for a proper measurement of the target construct.	see, e.g., Ainsworth (2006), Butcher (2014)*, Lindner et al. (2017a*, 2017b*, 2018*), Lindner (2021)*, Mayer (1997), Saß et al. (2012)*
Coherence principle	Adding “seductive details” that are conceptually irrelevant can result in less deep processing of the core information, possibly due to priming of inappropriate schemas and limited WM resources.	Avoid unnecessary information such as “seductive details” in test materials (e.g., decorative elements) that add WM load but are not relevant to the task or the measurement of the core construct, especially if the seductive information is distracting in nature.	see, e.g., Lindner (2020)*, Mayer et al. (2001), Strobel et al. (2019)*
Signaling principle	Executive functions of attending, selecting, organizing, and integrating given information with existing knowledge can exceed WM capacity. Semantic and/or visual signals can support cognitive processing of complex information by guiding attention to the most important aspects of a material.	Use <i>semantic signals</i> such as preview summaries, section headings, labels and pointer words (e.g., “because”) for complex written explanations. Use <i>visual cues</i> (color, emphasis, pointers, etc.) to make relevant information more visually salient and support connections between corresponding text and picture information in multimedia displays.	see, e.g., Hegarty et al. (2010), Mautone and Mayer (2001), Moon et al. (2022)*, Richter et al. (2016), Saß et al. (2017)*, Saß and Schütte (2016)*
Spatial contiguity principle	Mental integration of spatially disconnected information is demanding of WM capacity. Proximity of corresponding text and images helps build connections between the information and reduce extraneous WM load during information integration.	Add chunks of text in closeness, proximity to semantically related parts (e.g., a picture) to avoid spatial split attention, enhance efficient processing, and to support a meaningful integration of corresponding information.	see, e.g., Jarodzka et al. (2015)*, Moon et al. (2022)*, Moreno and Mayer (1999), Saß et al. (2017)*
Temporal contiguity principle	Mentally integrating sources of information that are separated by time places a burden on WM. Presenting information simultaneously or close together in time (provided they do not compete for the same sensory channel) reduces WM load.	Present related verbal and pictorial information simultaneously and in non-competing ways (e.g., as an animation with a simultaneous narration), if supporting test-takers' mental model construction reduces task-irrelevant cognitive load.	see, e.g., Ginns (2006), Mayer and Anderson (1992)
Static media hypothesis	Static illustrations tend to reduce extraneous processing and promote active processing of information (e.g., imagery or reasoning) compared to animations, which may facilitate mental processes but can also introduce passive viewing (underwhelming effect) or lead to WM overload (overwhelming effect).	Consider using static images or sequential pictures over animations (even when presenting dynamic processes) and encourage the viewer to “mentally animate” sequential pictures, if understanding a process is a relevant prerequisite for the measurement of a target construct.	see, e.g., Hegarty (2004), Lowe (2003), Mayer et al. (2005)
Segmenting principle	Viewer-controlled pace of a presentation or animation allows to properly integrate presented information to build a mental representation while avoiding WM overload.	Break up complex information or animations into segments/chunks and give test takers control over the pace at which they view the segments. Allow user control of speed, or play/pause in animations to manage WM load in complex tasks.	see, e.g., Mayer and Chandler (2001), Mayer et al. (2019)
Pre-training principle	Presenting basic information (e.g., terminology, parts of complex processes) in a pre-training can help to reduce WM capacity that is needed during more complex mental model construction of the main material.	Consider offloading mental demands by introducing general or complex information in a familiarization phase in which test-takers are, for example, informed about item formats in a test, task requirements, technical terms and functions (e.g., in interactive tasks) or provided with required prior knowledge before they solve the target items.	see, e.g., Mayer et al. (2002), Mayer and Pilegard (2005)

Note. WM = working memory.

*Indicates research studies explicitly focused on assessment contexts and materials (unmarked references are focused on learning contexts and materials).

by the task (e.g., see Lindner et al., 2018; Saß et al., 2012). By contrast, *decorative pictures* can be defined as task-irrelevant visual additions that are not required to solve an item and are usually added to tests with the goal of enhancing test-taking pleasure. Experimental findings indicate that adding decorative elements (such as attractive photographs) to test items does not enhance motivation (Lindner, 2020), yet in contrast to research on seductive details in learning materials (e.g., see Wiley, 2019), decorative elements do not seem to significantly harm test-taker performance by distracting them from the main task (Berends and van Lieshout, 2009; Cooper et al., 2018; Lindner, 2020).

Several studies in the assessment field have examined the effects of including representational pictures that visualize task-relevant information from the test item stem (e.g., as compared to text-only items). Research from controlled experimental studies (e.g., Lindner et al., 2017a,b, 2018, 2020; Lindner, 2020, 2021; Ott et al., 2018; Saß et al., 2012), has shown a cognitive benefit from representational images in terms of improved task performance. An eye-tracking study by Lindner et al. (2017a), further revealed the potential of representational pictures to improve effective information processing by supporting students' mental model construction as well as their decision-making processes. Eye movement data showed that the picture attracted attention early in the onset of the item on-screen (i.e., mental scaffolding) and in the later phase of the decision-making process (i.e., mental model updating) and that students needed less time to read the accompanying text when a representational picture was present. Studies also suggest that adding representational pictures to text-based test items has the potential to improve self-reported item-solving satisfaction (e.g., Dewolf et al., 2015; Lindner et al., 2018, 2020; Lindner, 2020) and lowers the incidence of disengaged rapid-guessing behavior (Lindner et al., 2017b, 2019; Wise et al., 2009).

Taken together, these findings suggest that representational pictures help to provide cognitive scaffolds to support students' understanding of the task they are asked to solve. However, the effects of representational pictures also seem to depend at least to some extent on the specifics of the layout, the task and domain (e.g., see Hu et al., 2021; Lindner, 2021, for reviews). For example, even the specific layout of a picture (e.g., a linear format vs. a circular arrangement of the same 24-hour clock) can affect its impact on different tasks (see Schnotz and Kürschner, 2008). Thus, it is important not only to consider the display *content* but also its *format* and how well it supports the cognitive task to be completed.

Graphs and charts

Many different kinds of graphs and charts are used in education to convey quantitative information. In assessment, these types of pictures can generally be classified as *informative* and/or *organizational* pictures, since they display additional task-critical information that is complementary to information provided in a verbal format (see Lindner, 2021). Graphs are used to assess skills of data interpretation and graph generation, but they can also be used as a stimulus for unrelated measures such as speaking or writing skills.

Multiple studies in cognitive science have shown that graph comprehension is influenced by prior knowledge and long-term schema, such as knowledge of how to read a specific type of graph, as well as a person's schemas and assumptions about the referents represented in the graph. Most importantly for the assessment context, graph comprehension is also affected by bottom-up factors such as graph design features, as well as the complexity of the graph and the data represented (e.g., see Freedman and Shah, 2002; Kozhevnikov et al., 2007; Ratwani and Trafton, 2008; Shah, 2002; Shah and Freedman, 2011; Shah et al., 2005; Shah and Hoeffner, 2002).

Since particular conventions govern the formatting and design of different graph types, viewers must know these conventions in order to interpret a graph correctly (Hegarty, 2011; Ratwani and Trafton, 2008; Shah et al., 2005). Whether to include graphs and complex tables can therefore be a sensitive decision in assessment materials. In cases where differences in graph reading skills can introduce construct-irrelevant variance (i.e., when graph reading is not part of the targeted construct), supporting accurate interpretation of the data represented, by including design features to scaffold and guide graph comprehension, is especially critical for valid interpretation of test-taker performance. For example, in assessment tasks that used graphs as stimuli for speaking tasks in tests of language skills, the number of visual chunks in a graph (i.e., the amount of information to be integrated, which contributes to general mental effort when processing graphs) predicted performance (Katz et al., 2004; Xi, 2005). Moreover, reducing graph complexity and giving participants additional time to process the graph information in advance of the speaking task reduced construct-irrelevant variance arising from performance differences between students with differing degrees of graph familiarity (Xi, 2005, 2010).

Eye-tracking studies are especially well-suited to understanding how individuals read graphs and how different layout decisions impact cognitive information processing and the steps that occur as students answer questions about the information conveyed by a graph. Carpenter and Shah (1998) found that the majority of graph readers' time was spent looking at the axes and labels. Moreover, participants reexamined the same areas over and over, suggesting that mentally maintaining all of the displayed information in WM was challenging, especially for more complex, higher-dimensional graphs. Applying graphical features in these areas to capture viewers' attention and guide interpretation (e.g., salient visual signals to direct attention or Gestalt grouping principles to indicate connections) could help viewers to process the graph and free-up more WM capacity for interpreting the data (Shah and Hoeffner, 2002; Shah et al., 1999).

These methods have also been used to empirically study the effects of including graphs in assessment items. An eye-tracking study by Strobel et al. (2018) showed that adding task-irrelevant data to a graph can significantly increase task-processing time, error rates, and reported cognitive load. In particular, the addition of task-irrelevant data series (i.e., second factor) was detrimental, whereas the addition of task-irrelevant data points was less harmful, indicating that test designers should reduce graph information to the relevant core, if graph reading skills are not the targeted construct. Task-irrelevant additions to graphs should generally be avoided, even if they are not all equally harmful. For example, seductive text and seductive decorative pictures did not affect

students' performance, but eye-tracking data showed that the processing time (especially on the seductive content) was significantly increased (Strobel et al., 2019). Finally, to reduce task-irrelevant cognitive load, test developers should make sure that they display the graph type that is best suited for the task goal (e.g., line graphs for reading trends; e.g., Strobel et al., 2016).

Dynamic visual media: animations and videos

When the information to be communicated is dynamic in nature, such as a process that occurs over time or a system in action, it may seem logical to use dynamic playable media such as video or animations to convey that information. Well-designed dynamic visualizations can more directly represent dynamic processes than static images (e.g., see Lowe and Boucheix, 2016), but cognitive benefits of animated graphics over static representations have not been consistently found for learning (Bétrancourt and Tversky, 2000). Decades of research in cognitive science indicate that animations can be difficult for viewers to process and comprehend (e.g., see Höffler and Leutner, 2007 for an overview) and therefore should probably be used somewhat sparingly in assessment items.

The question of when to use dynamic rather than static representations in assessment is complicated by inconsistent findings on the advantages and disadvantages of different kinds of dynamic playable representations in educational settings, making it hard to conclusively establish when to use video or animation rather than static images (Berney and Bétrancourt, 2016; Höffler and Leutner, 2007). Nonetheless, Bétrancourt (2005) provides some helpful suggestions in the context of learning materials to answer the question "Do I really need to use an animation?" She suggests that animations may be beneficial when communicating changes over time if learners may not be able to infer the steps between static images; or when users are novices, or are under a very high cognitive load, and may not be able to form a mental model of dynamic phenomena without actually seeing them. She also suggests using animations for particular educational goals—for example, to visualize phenomena that are not easily directly perceptible (e.g., too fast, too small, or too dangerous to observe directly). However, it is known that prior domain knowledge, as well as visuospatial cognitive skills, impact how readily and effectively students can benefit from dynamic educational resources (e.g., see Berney and Bétrancourt, 2016), and this should also be taken into consideration when making design decisions about dynamic visualizations.

If a dynamic visualization becomes part of an item, test designers should consider established instructional design guidelines such as matching the type of visualization to what is being represented (Ainsworth and VanLabeke, 2004), giving the user control over the speed of the animation (as well as play, pause, rewind, etc.) so they can match the playing speed with their speed of comprehension (Schwan and Riempp, 2004), and providing complementary verbal-auditory information to scaffold the information without overloading visual working memory (Huff and Schwan, 2012). It can also be a helpful design strategy to break apart complex processes into serialized static pictures or shorter animations that show different parts of causal chains, with corresponding narrations and explanations of how they are related to each other (Narayanan and Hegarty, 1998, 2002).

Designing tasks for process data modeling, analysis, and reporting

As mentioned above, digital assessment platforms have made it possible to include interactive response formats, such as drag-and-drop, and interactive components and multimedia stimuli, such as text-to-speech, key-term translations, online tutorials, and calculators (Bartram and Hambleton, 2005; Ercikan and Pellegrino, 2017). With purposeful back-end design, process data can capture test-taker interactions along with their respective timing for later modeling, analysis, or reporting. This includes interactions with on-screen elements, in addition to interactions related to entering the response, such as drag-and-drop actions, keystrokes, and mouse clicks. In this regard, a key benefit of digital assessments and technology-enhanced items is the potential to collect information about the interactions of test takers with the item functions while completing a task (Ercikan and Pellegrino, 2017).

There are different use cases for process data in educational assessment. Process data can be used: (a) to investigate potential user interface and experience issues that are irrelevant to the construct in pilot studies or experimental studies to make sure that the interface design or the response format choices are functioning in the way they are intended to function (e.g., Arslan et al., 2020; Moon et al., 2020); (b) to make fine-grained inferences about test-takers' cognition, such as information processing, decision making (e.g., Katz et al., 2017; Oranje et al., 2017; Lindner et al., 2017a,b), or higher-level cognition such as knowledge, skills, or strategies (e.g., Greiff et al., 2018); (c) to detect rapid guessing and aberrant response behaviors (e.g., Wise, 2017); (d) to validate score meaning (e.g., Ercikan and Pellegrino, 2017) and support score reporting (e.g., The Nation's Report Card, <https://nces.ed.gov/nationsreportcard/>); and e) to provide feedback to test takers (e.g., Wise et al., 2006) or proctors (e.g., Wise et al., 2019). See also Nikolay et al. (2022, this volume), for a thorough review of computer-based process data analysis in education and further use cases of process data in formative assessment (i.e., assessment for learning).

However, these low-level logged interactions do not by themselves represent test-taker knowledge, skills, and abilities. The context of the interaction (i.e., the preceding and subsequent test-taker actions or system events) needs to be considered and aggregated (e.g., see Goldhammer et al., 2021). Moreover, there is always uncertainty associated with inferences made from process data, since captured behavior patterns can also be related to off-task behavior or cognitively disengaged test-taking behavior, such as mind wandering or interacting with a task without being cognitively engaged.

In order to make valid and relevant inferences about cognitive processes from process data, it is important to have theoretically-grounded approaches for process data modeling (e.g., Forsyth et al., 2014; Zapata-Rivera and Arslan, 2021). It is also important that interactive task design is grounded in a *cognitive model*—that is, a theoretical account of the processes and steps assumed to occur

during that cognitive activity. A cognitive model is not the same as a target construct—a target construct, such as physics knowledge or computer programming skills, is what we hope to measure through an assessment, defined in a way to allow assessment developers to devise a task to elicit evidence from which they can infer a student’s competency in that construct (e.g., see Evidence Centered Design, [Mislevy et al., 2003](#); and In-Task Assessment framework; [Kerr et al., 2016](#)). This can in principle be done without any formal model of the cognitive processes involved in engaging in those activities ([Leighton and Gierl, 2007](#)).

By contrast, one can use a cognitive model to describe and/or explain the mental steps or processes that occur when test takers engage in an activity. This provides a cognitively grounded account of the mental processes associated with the construct targeted by a task. For problems in a given domain, we may attempt to specify the kinds of cognitive processes that are recruited and identify steps or strategies that are commonly applied by test takers who are engaging in solving specific problems (e.g., see [Goldhammer et al., 2021](#)). This can also include individual differences in the relevant processes and solution steps. For example, depending on test-taker proficiency, due to different starting points of prior knowledge levels, we may expect differing quality of mental representations of problems or situations, and different approaches to reasoning and problem solving (e.g., [Chi et al., 1981](#); [Larkin et al., 1980](#); [Newell and Simon, 1972](#); [Newell, 1990](#); see also enacted constructs: [Gorin, 2006](#); [Keehner et al., 2016](#)).

Thus, when designing an assessment task, if we want to make evidence-based inferences from process data about cognition, a cognitive model is needed in which the mental and behavioral processes that are expected to occur during a certain activity are specified. This theoretical grounding can then be used to design interactive elements that not only support, frame, or constrain the activity to the specified processes, but that will also make it possible to find evidence of the expected cognitive steps or processes in the log data of actions as recorded when the test taker interacts with the task elements. If we wish to apply quantitative scoring rules or qualitative criteria for evaluating the processes inferred from the log data, we also need to specify the ways in which the relevant cognitive processes might differ in individuals with more or less proficiency, and how the process data arising from the task would reflect those differences (e.g., [Katz et al., 1998](#)).

From this perspective, once a task or item is envisioned, there are some iterative steps that can help to ensure that it will produce process data that is able to support fine-grained and targeted inferences about test takers’ cognitive processes. These iterative design steps are illustrated in [Fig. 1](#).

As [Fig. 1](#) shows, the first foundational step is to model the mental processes that are associated with the target construct in the context of the proposed task or item (i.e., determine the required solution process or expected reasoning steps that test takers will engage in to provide their response). The next step is to conceive and design a set of activities that would elicit these mental steps and capture evidence of them in the form of external actions, such as test-taker interactions with tools and technology-enhanced response formats that reflect the steps in the reasoning process (e.g., interaction with a calculator, drag-and-drop response actions). By designing the task or item with interactive affordances that require or encourage construct-related external actions, which capture the sequences of test takers’ reasoning processes as they unfold in time, the task or item has the capability of “embodying” students’ mental steps in its process data outputs, to provide observable evidence of these internal processes.

Once these two key design steps are accomplished, it is helpful to generate research questions and hypotheses about construct-relevant observable behaviors (e.g., action sequences that indicate misconceptions; potential range of tool use patterns such as calculator use) and ensure that the logged actions include the dimensions and the details needed to distinguish construct-relevant individual differences among test takers in the anticipated range of key behaviors. If, during this phase, it becomes evident

Fig. 1 Iterative steps in designing tasks for process data modeling, analysis, and reporting.

that the current design of the task is not able to provide evidence for the expected range of hypothesized construct-relevant observable behaviors, the design should be revised accordingly. A further important related step is to document the hypothesized behaviors so that there is a theoretical basis for making inferences about student knowledge, skills, and abilities in any subsequent process data modeling and analyses. Usability and/or pilot studies should also be conducted, with further revisions to the item or task after these, if necessary, to ensure the task design and the process data it produces include the properties and features needed to make valid inferences about the mental processes associated with the target construct.

The resulting process data from the task or item should be analyzed from both a top-down theory-driven perspective (i.e., based on the previously documented research questions) and a data-driven exploratory approach (i.e., exploring the process data to discover new insights). If the exploratory analyses reveal additional constructs or hypotheses that were not anticipated or have not been encountered before, the task designer should revisit the first stages of the design process (modeling the mental processes and documenting hypothesized behaviors) and the new observations and inferences should be incorporated.

Ideally, tasks resulting from this design approach should be evaluated to establish whether they are eliciting the theorized cognitive processes. Cognitive scientists have developed a range of research methodologies to support such inferences, which can be used for task evaluation. These include asking individuals to verbalize their thoughts as they work through a task (think aloud methodology; e.g., see [Somerén et al., 1994](#) for an introduction) or examining how individuals attend to and shift their gaze between different parts of a stimulus (eye tracking methodology; e.g., see [Holmqvist et al., 2011](#) for an introduction). These methods can produce external traces of the presumed mental processes, known as *protocol data* (and, in fact, process data is another form of protocol data, in that the log of test-taker interactions reflects the invisible mental processes occurring during task completion as they unfold in time). Validation studies using such methods can help researchers to evaluate whether the processes and steps predicted by the cognitive model are indeed being observed during the activity ([Keehner et al., 2016](#)).

Conclusions and future directions for researchers and practitioners

Advancements in technology have drastically increased the design options for interactive digital assessments and technology-enhanced items. With these increased options, it is more critical than ever to consider the constraints of human cognition when designing items or tasks, so as not to put the validity of the interpretation of the test outcomes at risk (see [Principles for cognition-centered task and item design](#)). To this end, we have briefly reviewed and summarized some key insights from the decades of relevant research findings and principles from the cognitive and learning sciences, to encourage assessment developers, testing companies, and educational institutions to apply a cognition-centered design approach instead of a technology-centered approach.

Although there are principles for cognition-centered design (see [Table 1](#)) that may provide some guidance, it is important to further investigate the effects of specific design choices on test-taker cognition and performance. Therefore, as the field of assessment design principles is still evolving (and it cannot be taken for granted that we can simply transfer all of the principles from learning to testing materials), it is critical to conduct more research in which the effects of design choices are investigated by conducting think-aloud studies, eye-tracking studies, and randomized, controlled experiments, so that researchers can develop cognition-centered theories about the design of digital assessment tasks and technology-enhanced items. Also, it is important that researchers disseminate their findings and communicate practical implications for assessment professionals.

Moreover, to be able to make valid, fine-grained inferences about test-taker cognition from digital assessments, we have argued that it is important to design tasks and items with the explicit goal of capturing meaningful and interpretable process data (see [Designing tasks for process data modeling, analysis, and reporting](#) and [Fig. 1](#) for detailed suggestions on how to design digital tasks and items for process data). Designing for valid inferences about test-taker cognition from process data requires cognitively-grounded design considerations at both the front-end and the back-end of tasks and items to ensure that externalized construct-relevant mental processes are captured in the log files.

To put all of the above-mentioned suggestions, principles, and methods into action, content experts, item writers, and assessment developers need to work with an interdisciplinary team that involves cognitive scientists, user experience and user interface designers, psychometricians, and software developers, from the onset of digitally-based task creation and design, and throughout the development process. Designing tasks and items with cognitive processes in mind helps to support the overarching assessment goal of making valid inferences about test-taker cognition.

After more than 10 years as a teacher and 25 years as a test developer, one lesson I have learned again and again: It's extremely easy to write a bad test question.

—Overheard in the hallway at a testing company.

Introduction

This article focuses on one facet of overall test development. It presents an overview on the nature of traditional item types typically used in educational measurement, and it describes the advantages and disadvantages each item type contributes to the test design, and, therefore, to test use and to test validity, reliability, and fairness.

For the purposes of this discussion, 'item' is used to describe all versions of what are typically known as test questions. Item as a general term here includes everything from individual discrete true-false questions, to multiple-select multiple-choice questions, to sets of items related to a single stimulus (e.g., a reading passage or a video clip), to prompts (e.g., essay questions), and to larger tasks (e.g., more complex sets of interrelated questions, often including test takers doing some kind of performance). This article also looks briefly at non-traditional item types, including technology-enhanced items and, as often used in noncognitive assessments, Likert-scale item types.

The larger context and guiding principle for this discussion is overall test development: "Test development or test construction refers to the science and art of planning, preparing, administering, scoring, statistically analyzing, and reporting results of tests" (Downing, 2010, p 159). (For especially useful overviews of test design and development, see Schmeiser and Welch, 2006; Downing, 2010; Odendahl, 2011; Lane et al., 2016.) That is, the writing of appropriate types of high-quality items directly contributes to the three guiding goals for all assessments: validity, fairness, and reliability, about which more will be said as we look at how these goals are reached during the process of item development. Although there are references to basic statistics (i.e., at the level of how test data informs item writing and reviewing), the scope of this article does not include any detailed discussion of psychometrics, information covered elsewhere in the encyclopedia. The focus of this discussion is on specific item types used in tests that are primarily designed to assess general cognitive skills and/or specific subject content in either academic settings (e.g., summative or formative classroom-based; admissions; student learning outcomes; large-scale assessments of state or national learning progression) or in career settings (e.g., screening for hiring; promotion within a corporation).

One major overall aspect of developing and administering an assessment is that the process is iterative, not linear, and, reflecting that process, this discussion is also iterative. That is, for instance, the text describes item types, then returns to discuss the major steps in item development, and then returns to discussing those steps as they function in different test design contexts, and then returns to discussing how they are evaluated in operational settings, and so on. The ongoing focus, however, is on the different kinds of item types most often seen in assessments.

Item types in the context of test design

The initial decisions around determining which item types are most appropriate for a given assessment evolve from the early stages of test design, which, in turn, are typically informed by test designers following procedures of Evidence-Centered Design (ECD) (For detailed discussions of ECD, see Mislevy et al., 2003; Mislevy and Riconscente, 2006; Zieky, 2014; Riconscente et al., 2016).

In brief, the process of ECD helps test developers—often working with external committees of subject-matter experts (SMEs)—systematically determine, and document rationales for, such test design decisions as precisely defining, among many other steps in the process, at least all of the following:

- the assessment's construct (or domain: the specific knowledge, skills, or other attributes [KSAs] to be measured for the clearly specified test-taking population),
- the timing,
- the number of items in a given test form,
- the item formats (e.g., the number of options for multiple-choice items; the descriptors in scoring guides, or rubrics, for constructed-response prompts),
- the test blueprint or test specs,
- the specific intended use of the test,
- whether the test will be norm-referenced or criterion-referenced (and, if the latter, possible cut scores),
- the initial high-level design of the likely test report,
- how the test will be made accessible,
- in what mode(s) the test will be administered (e.g., paper-and-pencil and/or via computer),
- what psychometric data will be collected,
- if/how different forms of the test will be statistically equated, and
- the intended test use.

At each stage, participants in the ECD process collect clear and definable rationales for every decision, linking specific test taker performance as evidence (specific claims defining that evidence) of their KSAs—the foundation to evaluating the assessment's validity—knowing, however, that the overall test development process is inevitably recursive and that many of these decisions will be revisited and emended during the entire process of developing and field testing early tryout versions of the assessment. (For useful overviews on general developments in assessment practices, see [Odendahl, 2011](#), and [Bennett and von Davier, 2017](#).)

General principles in selecting item types

As previously suggested, the ECD process, in brief, includes defining the following: the domain model (what KSAs are being measured); the claims (what we can say about test takers); the task models (precisely what we ask test takers to do to demonstrate their knowledge of the construct's KSAs); the evidence models (what we observe to substantiate those claims); and the overall scoring models (how items will be scored and how scores will be aggregated across items and what scores will be reported). From this foundational design work, item writers proceed to compose specific items that the test developers and the external SMEs think will best measure the KSAs of the assessment's intended construct.

Throughout the twentieth century, in large-scale standardized academic assessments, the most common item type has been the multiple-choice item. But as [Odendahl \(2011, pp 1–17\)](#) points out, for centuries back to early screening assessments for civil service employment in China during the Han Dynasty (202 BCE – 220 CE), the main item type was the essay, variations of which continued to be delivered well into the twentieth century. However, in the mid-twentieth century, with technical improvements in capturing and scanning answer sheets, multiple-choice was seen as being more objective and, given efficiencies, more cost-effective, while essay responses were viewed as a less reliable (and more subjective) way to assess skills or content. Many academic assessments include a large set of multiple-choice questions to sample students' knowledge in a broad domain (e.g., biology) and a few constructed-response questions to assess the students' ability to apply that knowledge (e.g., design a controlled experiment or analyze data and draw a conclusion).

'Item type' is defined by the specific response method used by a test taker. Response methods can include, for instance, selecting one or more options (e.g., multiple-choice and multiple-response multiple-choice, matching, re-ordering); selecting a cell in a grid; completing a graph; writing a short answer to a specific question; filling in a one- or two-word or more answer; composing a brief response; composing an extended response; performing one or more tasks; and so forth. Each item type can assess a wide variety of KSAs, and each item type can have a wide variety of components, as will be discussed.

Although multiple-choice is the most common (and well-known) item type of the last hundred years, it is but one of many possible item types, and even the multiple-choice item type itself comes in variety of flavors. But the first, high-level, decision about selecting which item type(s) to use in an assessment is, broadly speaking, choosing between the two main types of items: selected-response (SR) items (in which the test taker selects from a list of possible answers) and constructed-response (CR) items (in which the test taker constructs, or produces, an answer or performs one or more tasks). In brief, whereas selected response items allow reliable and economical measurement of a wide range of content in a short testing time, constructed-response items allow students to provide evidence of their ability to develop an argument, explain their reasoning with examples or data, draw graphs, or otherwise produce rather than merely recognize an answer.

Before looking more closely at each of these two main item types, we need to look at the specific primary advantages and disadvantages of each. Consider the standardized test to qualify for a state driver's license permit: there is usually a multiple-choice section consisting of some number of discrete items designed to assess whether the test taker is familiar with the basic rules of driving and traffic laws as outlined in a state department of motor vehicles manual (e.g., "Which of the following is indicated by a broken white line?"). However, even a perfect score on such a multiple-choice test section does not begin to indicate whether the potential driver has even rudimentary actual driving skills, so there is a second test section, a road test, in which the test taker has to demonstrate (by performing) an actual ability to drive on local roads, merge into moving traffic, parallel park, and so forth.

This combination of the two primary item types is analogous to traditional writing assessments: many tests combine one section of (SR) questions (an 'indirect' measure of writing ability) along with one or two (CR) prompts, each requiring the test taker to write an essay (a 'direct' measure of writing ability, which is often described as 'authentic' assessment). Why do so many writing assessments require both, instead of relying on just the multiple-choice or relying on just the essay(s)? The answer, as will be seen, helps delineate the advantages and disadvantages of each of these two major item types. (For a useful discussion of some of the reasons test designs might use CR along with, or instead of, SR item types, see [Livingston, 2009](#).)

Note that many innovative assessments (e.g., situational judgment tests) can use either SR or CR item types. That is, the item types often reflect, but they do not necessarily determine, the developments in new kinds of innovative assessments. The same affordances for each hold true: for instance, on one recently developed assessment of confirmation bias (designed to assess how willing test takers are to look at alternatives other than the ones they had previously chosen at random), the SR items measure the degree to which test takers demonstrate confirmation bias, but the CR responses reveal the test takers' rationales for their choices. Another recent assessment presents video performances dramatizing various kinds of potential conflicts in the work environment; some of these stimuli are followed by multiple-choice options, which quickly measure the test takers' understanding of, for instance, teamwork, while other stimuli are followed by questions asking the test takers to describe what they would do in that situation, with these latter item types helping measure the test takers' ability to think on their own of good ways to demonstrate teamwork while also capturing their rationales for given actions.

Selected-response items—some advantages and disadvantages

In brief, SR items are simple, versatile, effective, efficient, and accessible. They are relatively inexpensive to write, and they are relatively inexpensive to score. They can be easily delivered in both paper-and-paper and computer-based modes. They take test takers relatively little time to answer. For instance, some recent college admissions assessments had approximately 150 Reading, Writing, and Math multiple-choice items to be answered in 3 h, or an average of a little over a minute to answer each question, with per-item time on different sections ranging from 48 to 87 s; meanwhile, test takers had 50 min to respond to the single optional essay prompt. Given the large number of SR items that can be included in a relatively short time frame, SR items can efficiently assess a large portion of the intended construct, and, for the same reason, the SR items can provide higher reliability, including allowing for reliable subscores. That is, the power of SR assessments is not in any given item, but, rather, in the aggregate of a collection of items that cover a large portion of the construct.

However, SR items measure recognition, not actual test taker production. They do not reveal test takers' thinking processes. They allow for random guessing. They are often decried in anti-testing commentaries: educators in general do not trust them as accurate measurements of student abilities, and clients often see them as untrustworthy measures of educational attainment.

Constructed-response items—some advantages and disadvantages

In contrast, CR prompts require test takers to actively demonstrate their knowledge, rather than merely recognize and select correct answers. At the same time, including CR items that ask for written responses, for example, on an assessment means that test takers prepare by doing more actual writing and that their teachers include more writing in their instruction and classroom assignments. This, in turn, leads to greater face value in the educational community, and the 'washback effect' of encouraging test takers to do more writing has significant pedagogical value, as does the fact that CR items can provide real-world validity, can reveal the test takers' thought process and reasoning, and can assess test takers' ability to organize and clearly present complex information. The same general advantages apply to other, non-written, CR item types (e.g., those requiring an oral response or some other performative demonstration of the test taker's KSA).

Note, however, that some CR item types can in fact require test takers to write very little and in that sense can approximate what can be assessed more efficiently and inexpensively by SR items: such item types as fill-ins (requiring just one or just a very few words) or focused questions that require very short answers (one or just a few sentences) have many of the advantages of SR items, except that in general SR items are much more efficient to score and are still able to roughly assess the same KSAs, so the CR versions are not commonly used. (As AI scoring engines become more sophisticated, the difference in efficiency will inevitably begin to disappear.) Note that, for instance, some assessments in England have traditionally used CRs exclusively, including fill-in items, and these item types do not assess the KSAs any more accurately than do multiple-choice items, and they also require hand 'marking' by raters, which scoring itself can be unreliable. In contrast, many assessments in the United States require test takers to generate answers, for instance specific numbers on a math test, but the entries are still marked on scannable answer sheets so that the scoring can be done by machines, and not by human raters, thus combining the CR advantage of asking test takers to produce, not just recognize, correct answers with the SR advantage of fast and accurate scoring. Some writing assessments include 'sentence construction shift' SR items—here test takers must mentally rewrite the sentence according to specific criteria in order to choose the correct option that maintains the original sentence's meaning, which is another kind of blend of the properties of both CR and SR item types.

Because many CRs typically require more time to answer (especially essay prompts requiring anywhere from one paragraph to a multi-page response), fewer CR items can be included on a typical assessment, which thus leads to less coverage of the construct, and with fewer items on a test form, the result is lower reliability (without even taking into account the exacerbating challenge of maintaining high rater consistency during the scoring, another contributor to lower test reliability). It is also harder to ensure

comparability of different CR prompts, and therefore it is harder to equate different forms of the assessment. Although CR prompts can be relatively easy to develop, they require significantly more time and expense to score than do SR items. (Note that assessments with CR items that require written or oral responses are more and more relying on computer software for the scoring of the word-processed or spoken and recorded responses; use of AI scoring engines can significantly reduce the time and expense associated with all-human-scored assessments.) Finally, CR prompts are easier to memorize, and thus they can make assessments less secure. (For extended discussions of the methods, complexities, and challenges in developing and scoring CR and other performance assessments, see Baldwin et al., 2005; McClellan, 2010; Baldwin, 2012.)

It is important to note that it is misleading to claim that SRs are more objective than CRs. While it is definitely true that scoring SRs is generally objective and accurate in comparison to the potentially subjective human scoring (or even computer software trained on human scoring) of a response to a CR item type, an SR item can in fact have an objectively scored but in fact subjective answer (e.g., “Which of the following cities is the most fun for a traveler to visit?”), while a CR that asks a very specific question can be purely objective (e.g., “State the three primary examples the author presents to support his argument.”). Similarly, it is also misleading to claim that by their nature CR item types require higher-level thinking skills; CR items often do so, but so do well-crafted SR items.

Given the advantages and disadvantages of SR and CR item types, many assessments compromise by including some combination of both, taking into account the purposes, desired time allotment, budgeted costs, test development resources, and other aspects of the planned assessment. (For a history of writing assessment in the twentieth century and the decisions to use or not use essay prompts, see Elliot, 2005; for a survey of more recent practices in writing assessment, see Baldwin, 2020.) One general approach taken in some elementary and secondary school systems in the United States is to use constructed-response items in the classroom as formative assessment while relying on selected-response items for large-scale standardized summative assessments, especially when reporting at the institutional level.

Principles for developing items

Before looking in more detail at the two main item types, it is important to note some guiding principles that inform all item development.

As previously noted, the types of items are determined during the ECD process. For instance, typical academic summative assessments for elementary and secondary school students in the United States are often directly aligned to specific standards. Each state develops its own standards in order to define the specific construct for each subject at each grade level. That is, the standards define the KSAs that the students are expected to exhibit at the end of the academic year. Therefore, the SMEs and test developers who are designing and developing the assessments will develop test specifications that directly reflect those standards. Often the test design will specify that each item be directly linked to a specific and identified standard; at the same time, the test specifications will align the difficulty of each item to the appropriate level. The intent is to represent the range of item difficulty across the entire test. Item difficulty represents the item’s complexity, which is often based on the level of abstraction on Bloom’s taxonomy (1956) and/or at the correct level of the four levels of Webb’s ‘depth of knowledge’ (1997). These decisions about the test design are also closely related to whether the assessment is norm-referenced or whether it is criterion-referenced; the latter is more common for assessments at the elementary and secondary levels. Assessments may be aligned to specific curricula, and some curricula are defined simultaneously with the intended assessments. The same decisions are made in terms of specifying the cognitive load (and ‘working memory’) of the item types and the specific items. Often during the ECD process, item templates are created for each of the test’s item types, templates that specify the kinds of stimuli (e.g., length; lexical complexity; whether based on actual texts, or written specifically for the assessment), the kinds of content, and the kinds of options that the test designers feel will best assess the test takers’ KSAs for a given construct. These templates will also indicate, for instance, if the SR items will be primarily ‘discrete’ items (i.e., not part of a set of items) or if, instead, there will mostly be sets of items based on a single stimulus, or whether the assessment will include a combination of both kinds of items. Similarly, the overall test design will specify, for instance, whether there are composite items made up of different parts that together lead to a single overall score.

Meanwhile, for many tests (licensing, admissions, job screening), test takers are typically motivated and will do their best on any items; in contrast, test takers are often less motivated for tests where the stakes are low (e.g., large-scale assessments such as PISA, TIMSS, or NAEP, which do not report individual test taker scores but, rather, are used to assess progress across large populations of students). Low test taker motivation means that item writers must try to generate items that are more intrinsically of interest to the test taker population, and the item templates will reflect that goal. Dealing with low test-taker motivation can be especially challenging when using CR item types, although here at least test developers do not need to determine the motivation effect, since test takers cannot just randomly guess.

All item writers and reviewers must have deep understanding and knowledge of the requisite content or skill that is being assessed, and they must be carefully and extensively trained in all aspects of item writing, including, for instance, fairness, accessibility, and appropriate editorial style. The item writers might be any combination of professional test developers, trained outside freelance item writers, and external committee members (e.g., college professors in a specified discipline, often termed ‘subject matter experts,’ or SMEs). More recently, some testing companies have tried various ways to clone items, and some have even begun using automated item generation (Gierl, Lai, 2016).

Items for most assessments go through an extensive and rigorous set of review steps, including, for instance: initial item writing; two or three separate content reviews; separate formal fairness and separate formal edit reviews; and a final ‘fresh eyes’ review. (For outlines of fairness as an essential standard for test development, see [American Educational Research Association, American Psychological Association and National Council on Measurement in Education, 2014](#) and [Educational Testing Service, 2014](#). For a discussion of achieving fairness in assessments, and for a discussion of the kinds of sensitivity guidelines reviewers follow when reviewing items to ensure that there are no construct-irrelevant factors that could impact test takers, see [Camilli, 2006](#), and [Zieky, 2016](#).) At each step, all review comments are then resolved with the ‘owner’ of the previous step. Typically, completed items are collected in some kind of item pool or item banking system. When the different items are assembled into a test, following psychometric test specifications, the entire form often receives an overall final review, which includes insuring that the overall group of items fits the test content specifications, that there’s no unintended duplication of item content, and that no items ‘cue,’ or provide hints to, other items.

Items are typically tried out in different contexts before they are administered in an operational form. Test developers will often administer new item types in ‘cog labs,’ where a representative subpopulation of the intended test taking population will answer the try-out items. These test takers will then provide written and/or oral feedback: how they interpreted the items, what if any possible difficulties they had understanding what was being asked, and what cognitive processes they followed as they tried to answer the items. These cog labs help test developers ensure that the items are functioning as intended, i.e., that the items are measuring the intended construct.

For new assessments, test forms made of new items are often administered to small groups of test takers representative of the intended test-taking population, often as separate ‘field tests,’ so that psychometricians can generate statistical data before the items are assembled into final forms. The data in turn can identify items that are not performing as intended; can generate accurate statistics in order to be able to equate different forms; and can individually flag possibly problematic items that appear to be unfair to specific subgroups, termed differential item functioning (DIF). (For a discussion of DIF analyses, see [Camilli, 2006](#); [Zwick, 2012](#); [Zieky, 2016](#), pp 93–94.). Many well-established programs will embed pretest items into operational forms to determine item performance, although this practice is limited almost exclusively to SR items—CR items are often field tested separately in order to evaluate how potential test takers respond to a given prompt, but they are rarely if ever embedded into operational forms.

Developing common selected-response item types

The guiding principles described in [Principles for Developing Items](#) section inform both SR and CR item development, but there are processes specific to SR that are discussed in this section, with the focus being on multiple-choice items, the most common SR item type.

Whether a discrete item or an item in a set of items based on a single stimulus, the most common multiple-choice item type has a structure that typically includes the following:

- A stem, or the question, which can be open-ended (the answer completes a sentence, along the lines of, “Mixing sodium with water produces _____”) or closed (the stem ends typically with a question mark, along the lines of, “Which of the following is an example of a metaphor?”).
- Three or four or five options, with four being most common; however, note that [Rodriguez \(2005\)](#) and [Rodriguez and Haladyna \(2013\)](#) argue that three options are optimal.
- One key (the intended answer), with the other options being distractors. Note: Distractors that are intentionally written to represent specific types of common misunderstandings of the construct can be used to provide diagnostic feedback to the test taker and/or to the test taker’s teacher. Note that there are also multiple-select multiple-choice items (e.g., a test taker is required to indicate two answers from among six options—the test design would determine whether there is partial-credit scoring or whether credit is given only for test takers who mark both intended keys).
- SR items, discretized parts of sets, are often associated with a stimulus (a passage, chart, graph, map, audio or video clip, or other piece of work that provides the basis for the test questions).

When developing SR items, the goal is to have a single best answer, one that is defensible and that is directly linked to the KSAs defined as the construct being assessed and that is at the appropriate level of difficulty. There should be no errors in content or in grammar and usage. Wording throughout should be precise, concise, and accurate. The stem and key should reflect a clearly defined problem or task, and the stem should be focused specifically on a specific KSA from the construct. The options should be parallel, and they should be roughly the same length. The ‘distractors’ (options that are not the intended key) should be plausible, but they cannot be arguably correct responses. That is, there cannot be more correct answers than the test taker is asked to identify (some SR items, known as Multiple-Select Multiple-Choice, ask test takers to identify two or more correct answers). Distractors should also be mutually exclusive, or test takers can eliminate them as possible keys. Distractors should be wrong for non-trivial reasons. In general, more attractive distractors lead to more difficult items. “All the above” and “None of the above” are in general not acceptable options. To the degree possible, item writers should avoid using negative stems, but, if it’s deemed necessary to use them, the item writers should emphasize the negative word (“Which of the following is NOT an example of hyperbole...” “All of the following are examples of inert gases EXCEPT...”) so that test takers aren’t easily misled by construct-irrelevant phrasing of the stem. In general, item writers try to avoid anything possibly tricky or misleading in the language used in the item: if

test takers get a question wrong, it should be because they lack the required skill or knowledge, not because they have difficulty understanding the question or the options. Any accompanying graphs or images should be clear and appropriate. (For more detailed discussions of best practices in SR item writing, see [Roid and Haladyna, 1982](#); [Haladyna, 2004](#); [Schmeiser and Welch, 2006](#); [Downing, 2006a, 2006b, 2010](#); [Rodriguez, 2016](#).)

Developing and scoring constructed-response item types

Best practices in writing and reviewing CR prompts parallel those used in developing SR items.

However, the process of developing and scoring CR items includes the need to address challenges specific to CR item types.

CR (and other performance) item types range from entering numbers on a scannable answer sheet to fill-in-the-blank sentence completions to short paragraph responses to multi-page essays to in-class projects presented over two or more days. Assessments can require test takers to submit portfolios, which can include not just essays but also, for instance, video recorded performances. One alternative college admissions assessment required test takers to participate in team-based efforts to replicate a Lego structure; to participate in a group discussion; and to be interviewed. An American Sign Language assessment consisted of interactive interviewing of each test taker, with the ASL responses scored by two independent raters. A student learning outcomes assessment for college freshmen was intended to measure test takers' collaborative problem solving skills: the test required test takers to coordinate online with two other anonymous test takers in order to reach a group consensus, with raters evaluating the teamwork skills demonstrated by the test takers' online communications. Another college outcomes assessment asked test takers to present two directly opposing perspectives on a real-life topic. All of these use CR item types. (For a useful overview of performance assessments, see [Lane and Stone, 2006](#).)

But, in general, CR item types most typically require test takers to write essays of varying lengths. Note that although test takers increasingly use word processing software to generate their responses, many CR assessments are still given in a paper-and-pencil format. The items are typically used to assess test takers' writing and reasoning skills or their knowledge of specific content. For the former, prompts may ask test takers to develop a position on an issue or analyze a piece of writing; for the latter, test takers may, for instance, analyze historical documents, explain a scientific principle, or synthesize information from several passages. Stimuli for CR essay prompts can range from very brief one-sentence questions to two or more developed passages which test takers are asked to synthesize and reference in their responses. (For a useful overview of developing constructed-response and other performance assessments, see [Welch, 2006](#), and [Lane and Iwatani, 2016](#).)

SR item types can generally be scored by machine; CR items require raters to read, view, or listen to test takers' responses and to assign a score to each response. Typically, essays are scored on a 1–4 or 1–6 scale, using the sets of descriptors from a scoring guide (or rubric) that defines the typical qualities of a response at each score point along with exemplary responses at each of the score points, though many CR item types used in K12 content assessments are scored on a 0–2 or 0–3 scale. Some assessments have had much larger scales (e.g., 1–19). In general, the principle is that there should be as many score points as raters are able to consistently and accurately distinguish.

The two most common approaches to scoring CR prompts are with either holistic or with analytic rubrics. In holistic scoring, raters assign a single, overall score that reflects the overall quality of the response (it was originally called 'wholistically'). Holistic scoring has the advantage of being efficient; it provides a useful overview of student achievement. Analytic scoring (often called 'trait' or 'dimension' scoring) is increasingly common; this has been especially true for assessments of elementary and secondary school students in the United States. Here, raters assign separate scores for each of several traits, or dimensions (e.g., "Analysis & Argumentation," "Organization & Logic," and "Grammar & Mechanics" each scored on a separate scale, sometimes with traits being reported as subscores and also having different weights when combined for an overall reported score). Trait scoring can provide more detailed feedback, or diagnostic information, to test takers and their teachers (especially useful for assessments of content), but the scoring effort is significantly more time consuming. With either approach, large-scale assessments with CR item types have organized and standardized scoring procedures in order to ensure that all raters are using the same criteria when assigning scores.

When developing CR items, test developers will often themselves write out responses to prompts in order to evaluate how difficult it might be to generate a reasonable response in a reasonable time frame. Newly developed CR items are typically field tested in order for the prompts to be evaluated based on criteria reflecting, for instance, such questions as how well test takers seem to be able to engage the topic, whether responses are unfairly rewarded for outside knowledge that is not part of the intended construct, and how accurately and consistently raters are able to apply the scoring guide. During the scoring of the field test responses, test developers usually also select benchmarks, papers that are clear examples of what is representative of the qualities at each score point. In the early stages of the development of a new CR assessment, before it is administered operationally, the scoring guides are often changed to reflect what raters encounter while reading a range of test takers' responses. Occasionally changes are made to the time allotted for each task during the iterative process of test design and field testing of prompts, items, and entire test forms. Some programs will develop generic scoring guides for a large pool of prompts but will then also develop prompt-specific guides or notes for each individual prompt in order to help raters reach a high interrater reliability (i.e., the degree to which different raters independently give the same scores as do the other raters). Typically, during the scoring of operational CR prompts, essay responses receive two independent scores from two different raters, and if the two scores vary by more than a predetermined amount, the response typically goes to a third (often more experienced) rater to determine the final, reported score. During scoring, trained raters

are monitored by senior and more experienced scoring leaders. All efforts are made to ensure that the scoring is valid, reliable, and fair.

Although there are few assessments that rely exclusively on automated scoring engines, more and more scoring of CR item types is done with at least one ‘reading’ performed by computer software. Computational linguists have developed scoring engines for assessing writing, specific content, and math. While the initial development costs can be high, these scoring programs, once ready for operational use, are significantly less expensive and of course significantly more efficient than human scoring. (For further discussions of automated scoring of CR assessments, see [Ericsson and Haswell, 2006](#), and [Shermis et al., 2016](#). For further discussions of both human and AI scoring of CR item types, see [Educational Testing Service, 2021](#).)

Other item types

Technology, specifically the increased capabilities of computers (along with the creativity of task designers and item writers), has not only changed how CR item types are scored, but it has also led to a greatly increased use of technology-enhanced items (TEIs). TEIs rely on test takers being able to use computers to produce their responses (for either SR or CR item types, although the latter is far more common). Early and less technologically demanding TEIs included, for instance, item types such as asking test takers to use the computer’s mouse to highlight the appropriate sentence in a reading passage. More recent TEIs have included such item types as inline choice, grids, fill-ins, graphs, ordering events, and drag-and-drop. TEIs can be more engaging for test takers, can use realistic simulations, and can capture more aspects of a response than traditional items. For instance, drag-and-drop items allow test takers to construct an appropriate sequence rather than just recognize one ([Arslan et al., 2020](#)). In that sense, the drag-and-drop item type shares some of the advantages of CR item types, but it can be machine scored like SR items. The new item types and their many variations have given task designers more tools to use, but they have also increased the amount of information that task designers need to make appropriate decisions about which item types and features to use. TEIs have disadvantages as well as advantages and should not be used merely to add variety or novelty to a test without regard to their impact on the quality of the construct-relevant evidence provided by the test; accessibility can be a special challenge with TEIs. (For discussions for and against the argument that TEIs have the potential to better represent knowledge, skills, and abilities of students in a more authentic way compared to traditional multiple-choice items, see [Bryant, 2017](#), and [Scalise, 2012](#)).

Also worth mentioning is the Likert-type item. This item type is widely used in ‘noncognitive’ assessments of, for instance, test takers’ physical and mental health, attitudes, opinions, and other traits. Although common in anonymous surveys, this item type is also found in assessments designed, for instance, to measure an individual test taker’s personality. A Likert-type item asks test takers to rate themselves on some attribute, using a scale (e.g., numeric, as in 1–5 [from “Strongly Disagree” to “Strongly Agree”], or by descriptors, as in “Never,” “Sometimes,” “Always”). (For a brief but useful overview of this item type, see [McLeod, 2019](#).) However, such self-ratings can be misleading in that test takers may well intentionally select not what they actually think is an accurate self-description but, instead, what they think the employer or academic program wants to see (i.e., putting themselves in a positive light, or answering based not on their actual self-evaluation but instead on social desirability). As [Kyllonen \(2016\)](#) notes, “The forced-choice response format was designed to address the faking problem” in self-reporting (p. 201), since test takers have to select which of two similarly socially positive or similarly socially negative Likert-type statements best describes them (e.g., having to select between the two statements: “In mathematics I always try to do better than the other students in my class” and “In mathematics, I enjoy helping others to work well in a group”). Over the last two decades there has been a greatly increased use of these kinds of assessments used to measure personality traits ([Kyllonen, 2016](#)), primarily in the context of careers, but more and more also in the academic arena. Employers and academic programs are interested in candidates’ strengths and weaknesses in such psychological areas as motivation, ‘grit’ (or resiliency), creativity, leadership, and teamwork.

Glossary

Automatic Item Generation A process of generating test items with the aid of computer technology.

Cognitive Model for AIG A representation that highlights the knowledge, skills, problem-solving processes and/or content a student requires to answer test items.

Item Model A template that highlights the features in an item that can be manipulated to generate new items.

Key Features Cognitive Model A model used to guide item generation based on the relationships among the key features specified in the cognitive model, which include the attributes or features of a task that are systematically combined to produce meaningful outcomes across the item feature set.

Logical Structures Cognitive Model A model used to guide item generation based on the students' ability to use a concept across a variety of different content representations. The concept is often used to implement a formula, algorithm, and/or logical outcome.

Semantic-Based AIG The semantic-based approaches use information acquired from a semantic analysis of the content in a corpus or knowledge base. Semantics focuses on the meaning of a sentence which is often expressed using a structured combination of words.

Sequence-Based AIG The sequential-based neural network approaches are used to generate test items automatically. These approaches focus on generating test items by disambiguating and learning the primary characteristics from the content in a corpus or knowledge base to create test items.

Syntax-Based AIG The syntax-based approaches are designed to generate items by uncovering the underlying syntactic structures of the content in a corpus or knowledge base. Syntax is a description of how words are combined in sentences, where the syntactic structure of a sentence conveys meaning.

Systematic Distractor Generation A method for generating distractors where specific information related to errors and misconceptions is used to create plausible but incorrect options.

Introduction

Changes in educational technology are profoundly affecting educational testing. Developers of international, national, and local educational tests are now implementing computer-based tests at an extraordinary rate. The world's most popular and visible achievement test—the Program for International Student Assessment (PISA) which was developed, administered, and analyzed by the Organization for Economic Cooperation and Development (OECD)—is computerized. While the first five cycles of the test administered were paper-based, 58 of the 72 participating countries in PISA 2015 took the computer-based version. The number of countries which opted for CBT increased to 89% (70 of the 79 participating countries) for PISA 2018 in keeping with the OECD view that computer-based testing has become part of the educational experience for most students (OECD, 2019). To cite another recent milestone: 2016 marked the first academic year that US states administered more computers than paper-based tests (He and Lao, 2018). Provincial agencies in Canada are also moving to computer-based testing. Alberta Education, for example, introduced computer-based tests in 2010, but limited its use to the Grades 6 and 9 achievement testing programs. Computer-based testing has now expanded to include all provincial tests including the achievement tests as well as the Grade 12 diploma examinations. These examples demonstrate that computer-based testing has quickly become the hallmark of 21st-century assessment and that testing

agencies are either administering their tests using a computer or migrating to this platform. Computer-based testing offers important benefits. For example, computers permit testing on-demand which means exams can be administered using a schedule that is flexible, frequent, and convenient. Computer-based testing allows students to take the test during instruction. Items on computer-based tests are scored immediately thereby providing students with feedback.

But the advent and growing popularity of computer-based testing has also raised daunting new challenges, particularly in the area of item development. Educators must have access to large numbers of diverse, high-quality test items to effectively implement computer-based testing because items are continuously administered to students. Hence, thousands of new items are needed to develop the test item banks necessary for computer-based testing. A bank is a repository of test items, which includes both the individual items and item characteristics. These banks must be initially created then constantly replenished to ensure that students receive a continuous supply of items while, at the same time, limiting item exposure. Unfortunately, educational test items, as they are currently created, are time consuming and expensive to develop because each individual item is written, initially, by a subject matter expert (SME) and, then, reviewed and revised by groups of SMEs to ensure the items are reliable and valid (Haladyna and Rodriguez, 2013; Lane et al., 2016). Hence, test item development is one of the most important problems that must be solved before educators can fully migrate to computer-based testing and realize the benefits of formative assessment.

Automatic item generation for test development

Automatic item generation (AIG) is a method for creating test content that can be used to address this item development challenge (Gierl and Haladyna, 2013; Irvine and Kyllonen, 2002). AIG is a rapidly evolving research area where cognitive and psychometric modeling practices guide the production of tests that include items generated with the aid of computer technology. AIG researchers and practitioners have adopted two different methods for generating test items—the first method relies on the use of templates to structure the testing content while the second is template free, relying, instead, on the use of advanced statistical techniques such as natural language processing and machine learning to structure the testing content. In this chapter we describe, illustrate, and evaluate these two methods.

Template-based AIG

Templates are commonly referred to as item models. An item model is a template that specifies the features in an item that can be manipulated to generate new items (LaDuca et al., 1986). Item modeling can be embedded in a three-step approach for generating test items (Gierl and Lai, 2013, 2016). In Step 1, the content for item generation is identified by the SME. This content is identified using design principles and guidelines that highlight the knowledge, skills, and abilities required to solve problems and perform tasks in a specific domain. A cognitive model for AIG is a summary that organizes the cognitive- and content-specific information into a structured representation of how the SME expects students will think about and solve problems. Two types of cognitive models are often used to generate educational test items (Gierl and Lai, 2017). The first is called the logical structures cognitive model. It is most suitable for measuring students' ability to use a concept across a variety of different content presentations. The concept is often used to implement a formula, algorithm, and/or logical outcome. Examples of logical structures cognitive models for AIG can be found in the content areas of science (Gierl and Lai, 2017; Gierl et al., 2016) and mathematics (Gierl and Lai, 2016; Gierl et al., 2015). The second is called the key features cognitive model. It is used when the attributes or features of a task are systematically combined to produce meaningful outcomes across the item feature set. This model is most suitable for measuring students' ability to assemble and apply key features within a domain as well as to solve problems using these key features. Examples of key features cognitive models for AIG can be found in the medical content areas of abdominal injury (Gierl et al., 2018), infection and pregnancy (Gierl and Lai, 2016), chest trauma (Gierl and Lai, 2018), hernia (Gierl and Lai, 2013), post-operative fever (Gierl et al., 2012), and jaundice (Gierl and Lai, 2017).

Cognitive models contain constraints. Constraints are rules specified by the SME that, in turn, are applied to the content in the cognitive model. Without the use of constraints, all the content in each part of the model would be combined to create new items. However, many of these combinations would not produce items that are sensible. Constraints serve as descriptions of conditions that must be applied during the assembly step (i.e., Step 3) so that meaningful items are generated. When the goal of item generation is to produce large banks containing many similar items, a relatively small number of constraints are used in the cognitive model. Alternatively, when the goal is to produce comparatively smaller banks of diverse items, a relatively large number of constraints are needed in the cognitive model. Hence, constraint coding is the method by which AIG captures the specific decisions, judgments, and rules used by SMEs to produce diverse, high-quality, content-specific test items.

In Step 2, an item model is developed to specify where the content from the cognitive model must be placed to generate new items. Item models provide the foundation for template-based AIG. An item model is a template created by the SME that specifies the features in an item that can be manipulated to generate new items (Bejar, 1996, 2002; Bejar et al., 2003; LaDuca et al., 1986). Item models also specify which parts of the assessment task can be manipulated for item generation. These parts include the stem, the options, and the auxiliary information. The stem is the part of an item which formulates context and/or content the student is required to answer. The options contain the alternative answers with one correct option and one or more incorrect options or distracters. Auxiliary information includes text, images, tables, diagrams, sound, and/or video, which are required to convey additional information required for examinees to answer the item. The stem and options can be divided further into elements. These elements

are denoted as non-numeric values (i.e., strings) and numeric values (i.e., integers). By systematically manipulating the elements, many items can be generated from one item model. For selected-response items like multiple choice questions, the stem and the complete list of options are required, including the correct option and distractors. For constructed-response items like short answer questions, only the stem and correct option are required to be specified in an item model.

One of the important differences between a constructed- and selected-response item is the outcome space for incorrect options or distractors. The incorrect options for a selected-response item are typically designed from a list of plausible but incorrect alternatives linked to misconceptions or errors in thinking, reasoning, and problem solving. Using a traditional item development approach, distractors are created by a SME that are specific to each item. But because AIG produces hundreds or thousands of items, an alternative approach is used to produce a correspondingly large number of plausible but erroneous distractors. This method is called systematic distractor generation (Lai et al., 2016). It is closely linked to the cognitive modeling step. Recall that to generate a stem and correct option, specific information must be collected in the form of a cognitive model (i.e., Step 1 in the three-step AIG process). Systematic distractor generation also involves specifying information related to errors and misconceptions in the form of a cognitive model in order to generate plausible but incorrect options. The process of modeling incorrect options is more complex compared to modeling the correct option because the item stem is constantly changing in a generative item development system. As a result, the small number of constraints required to ensure the information presented in the stem yields a correct response must be counterbalanced with a much larger number of constraints required to ensure the information presented in the incorrect options is erroneous but plausible. Also, more than one incorrect option is required for a selected-response item. Typically, three, sometimes four, incorrect options must be produced for each generated item.

In Step 3, a computer algorithm is used to place the cognitive model content specified in Step 1 into the item model developed in Step 2. Different types of software have been written to generate test items (e.g., Gierl et al., 2008; Gütl et al., 2011; Higgins, 2007; Higgins et al., 2005; Singley and Bennett, 2002). The most common approach for template-based AIG is to create an algorithm based on logical constraints. A logical constraints approach provides a straight-forward way to generate items using iterations where the generated content is specified as an element, as described earlier, and where each element contains all possible values to be displayed and substituted in each generated item. The presentation of the elements is organized in a cloze test format, where all values of an element can be displayed. Then, all combinations of the element values are assembled. With logical constraints, not all combinations of the values will produce meaningful test items. To prevent implausible combinations, the constraints defined by the SME in the cognitive model are used to limit the generated outcomes to those combinations that are deemed to be meaningful. The generation process can be described, conceptually, as an iterator that permutes through all combination of elements and, in the process, eliminates combinations (i.e., meaningless generated items) that do not meet the constraint requirements. In other words, once the content is specified in Step 1 and the template is created in Step 2, a logical constraints algorithm can be used to systematically place the content into the template in Step 3 to produce new items subject to the constraints in the cognitive model.

Example of template-based AIG

Because template-based AIG using item modeling is currently the preferred method for generating items, we present an elaborated example using content from the natural sciences. This example is drawn from the content area of botany where the student is required to identify a coniferous tree based on the characteristics of the tree. This example uses a key features cognitive model with systematic distractor generation.

In Step 1, a cognitive model for AIG is created. The model in this example was created inductively by a SME who was asked to identify and describe the information that could be used to differentiate coniferous trees. Three types of information are specified in the cognitive model for AIG. The first type of information is related to the main concept or problem and its associated scenarios. In our example, the problem is coniferous tree identification. Three associated scenarios include three different types of coniferous trees: Rocky Mountain Juniper, Limber Pine, and Tamarack. The second type of information specifies the relevant sources of information presented with the problem. In our example, four sources of information are presented: needle shape, needle group, needle length, and cones. The third type of information highlights the salient features, including the elements and constraints, for each source of information. The first component for a feature is the element. Elements contain content specific to each feature that can be manipulated for item generation. The second component for a feature is the constraint. Constraints serve as restrictions that must be applied during the generation process to ensure that content in the elements are combined in a meaningful way so useful items can be generated. For example, the needle shape feature includes three elements and three constraints where the constraints in this task are the correct option as shown in brackets: scaly, needle shaped leaves (Rocky Mountain Juniper), triangular needles (Limber Pine), and needles that are flattened above and keeled below (Tamarack).

In Step 2, the item model is created (see Table 1). The item model contains the template that will be used to generate test items. It also specifies the elements for the features. Four sources of information are included: needle shape, needle group, needle length, and cones. Each source of information contains unique elements: needle shaped leaves, triangular needles, and needles that are flattened above and keeled below (needle shape feature); opposite pairs along the branch, five-needle tufts, 15–60 need tufts (needle groups feature); 12 mm, 8–20 cm, 2–5 cm (needle length feature); berry-like seed cones, cylindrical seed cones, red and pink broadly ovoid seed cones (cone feature). The same logic is also used to produce the incorrect options using the systematic distractor generation method. Distractor 1 is Yellow Cedar. This coniferous tree shares some, but not all, of the elements with Rocky Mountain Pine. For instance, a Rocky Mountain Pine and a Yellow Cedar both contain scale-like needles. As a result, Yellow Cedar is a plausible but

Table 1 An item model for generating botany test items.

Stem	A first-year forestry student is hiking through Jasper National Park. He comes across a coniferous tree with <NEEDLE SHAPE> that are in <NEEDLE GROUPS> and measure <NEEDLE LENGTH> in length. Along the branches are <CONE>. These characteristics best describe which coniferous tree?
Elements	<NEEDLE SHAPE> 1. scaly, needle shaped leaves (RJ) 2. triangular needles (LP) 3. needles that are flattened above and keeled below (T) <NEEDLE GROUPS> 1. opposite pairs along the branch (RJ) 2. five-needle tufts (LP) 3. 15–60 needle tufts (T) <NEEDLE LENGTH> 1. 12 mm (RJ) 2. 8–20 cm (LP) 3. 2–5 cm (T) <CONE> 1. berry-like seed cones (RJ) 2. cylindrical seed cones (LP) 3. red and pink broadly ovoid seed cones (T)
Options	Rocky Mountain Juniper (RJ) Limber Pine (LP) Tamarack (T) Yellow Cedar (scale-like needles like the Rocky Mountain Pine) (YC) Jack Pine (triangular needles like the Limber Pine) (JP) Subalpine Larch (ovoid red seed cones like the Tamarack) (SL)
Key	Rocky Mountain Juniper (RJ) Limber Pine (LP) Tamarack (T)

erroneous option because it shares some but not all of the elements related to Rocky Mountain Pine. An incorrect option can be selected from this distractor model for inclusion in the generated item whenever it shares some but not all of the elements with the correct option.

In Step 3, the logical constraint algorithm assembles the content specified in an item model, subject to elements and constraints described in the cognitive model by the SME for both the correct and incorrect options. Iterations are conducted to assemble all possible combinations of elements and options, subject to the constraints. The outcome of the Step 3 assembly process is shown in Fig. 1. The model used in this example is small and simple because it is used to illustrate key concepts in template-based AIG. Item generation in operational testing programs is much more complex and often includes large cognitive models that address one problem with 4–7 different scenarios, 5–7 different sources of information, and 8–12 different features.

Evaluation of template-based AIG

Template-based AIG is based on item modeling. An item model specifies the parts and content in the task that will be manipulated to create new test items. Item modeling is flexible because it allows SMEs to create content for tests that are administered at different levels in the education system, for a wide range of purposes, and for different subject areas using a range of item formats and item types. Item modeling also allows SMEs to create diverse, complex, and high-quality items using an approach that is both efficient and cost effective. For these reasons, template-based AIG using item modeling is currently the preferred method for generating items. But template-based AIG has one important limitation. It relies on the SME's ability to create clearly structured cognitive and item models to guide the generation process. However, some content areas on educational tests do not permit an explicit disambiguation and extraction of features. For example, reading comprehension test items can be used to evaluate students' inferential knowledge. Reading comprehension items are designed to assess students' ability to evaluate the main idea and the sentiment of the reading passages of varying genre, length, and types. Generating test items using template-based AIG is challenging in a content area like reading comprehension because of the complexity required to identify and capture the features related to the correct option and to manipulate these features to create new items. For example, to create cognitive models to produce inference test items in reading comprehension, the SME must identify all text features (e.g., words, phrases, and sentences) used as evidence to support the key answer (e.g., overall sentiment, main topic, or theme). Without any systematic methods to analyze the deep semantic connections between the text features, and the overall themes, main ideas, and the sentiment presented in the text, this can be a challenging and laborious task for SMEs.

1. A first-year forestry student is hiking through Jasper National Park. She comes across a coniferous tree with scaly, needle shaped leaves that are in opposite pairs along the branch and measure 12 millimeters in length. Along the branches are berry-like seed cones.

These characteristics best describe which coniferous tree?

- A. Jack Pine
- B. Yellow Cedar
- C. Subalpine Larch
- D. Rocky Mountain Juniper *

*correct option

2. A first-year forestry student is hiking through Jasper National Park. She comes across a coniferous tree with triangular needles that are in five-needle tufts and measure 8-20 centimeters in length. Along the branches are cylindrical seed cones.

These characteristics best describe which coniferous tree?

- A. Jack Pine
- B. Limber Pine *
- C. Yellow Cedar
- D. Subalpine Larch

3. A first-year forestry student is hiking through Jasper National Park. She comes across a coniferous tree with needles that are flattened above and keeled below that are in 15-60 needle tufts and measure 2-5 centimeters in length. Along the branches are red and pink broadly ovoid seed cones.

These characteristics best describe which coniferous tree?

- A. Jack Pine
- B. Tamarack *
- C. Yellow Cedar
- D. Subalpine Larch

Fig. 1 Sample generated items in botany.

Non-template-based AIG and example items

To address the challenge of producing large numbers of items in a content area such as reading comprehension, non-template-based AIG can be used. Unlike the template-based method, the purpose of non-template-based AIG is to generate items directly with reduced human intervention. In other words, this method produces the stem, options, and/or auxiliary information without the use of an item model created by an SME. To accomplish this goal, the method relies on different types of natural language processing techniques and neural network systems which, in turn, draw on information from corpora and knowledge bases to generate the test items.

Three different approaches for non-template-based AIG have been described and illustrated. The first approach is syntax based. The syntax-based approach is designed to generate items by uncovering the underlying syntactic structures of the content in a corpus or knowledge base. Syntax is a description of how words are combined in sentences, where the syntactic structure of a sentence conveys meaning. Two commonly used syntactic techniques that can be used to generate items are syntax parsing and part-of-speech tagging (Brown et al., 2005; Chen et al., 2006; Danon and Last, 2017). Chen et al. (2006), for example, described a semi-automated grammar item generation system. Their system focused on identifying parts of the text or the sentences that could be used for a grammar test. Their non-template-based AIG method matched the regular expressions of the grammatical structure with predefined patterns to identify test items. Their system could also identify a set of plausible but incorrect options based on pattern matching. Brown et al. (2005) created a non-template-based AIG method that could generate items for assessing students' vocabulary knowledge. Their approach used a large lexical resource, WordNet, to generate six types of vocabulary knowledge items that measure students' ability to use definitions, synonyms, antonyms, hypernyms, hyponyms, and cloze questions. They focused on identifying the correct meaning of the word using the word and its part-of-speech tag information. Once the correct sense meaning was identified for the target word, their approach could also be used to identify a list of words that served as the correct and incorrect options. Examples of generated items using syntactic approaches are shown in Table 2.

The second approach is semantic based. The semantic-based approaches use information acquired from a semantic analysis of the content in a corpus or knowledge base. Semantics focus on the meaning of a sentence, which is often expressed using a structured combination of words. Semantic approaches for non-template-based AIG use natural language processing techniques such as topic

Table 2 Sample generated items using three non-template-based AIG methods.

Approach	Source	Sample test item
Syntactic	Chen et al. (2006)	I intend ____ you that we cannot approve your application. (A) to inform (B) to informing (C) informing (D) inform
	Brown et al. (2005)	Choose the word that best completes the phrase below: The child's misery would move even the most ____ heart. (A) torpid (B) invidious (C) stolid (D) obdurate
Semantic	Flor and Riordan (2018)	Text: Peter called on Monday./The particles from the Sun also carry an electric charge. Question: When did Peter call?/Do the particles from the Sun carry an electric charge?
Sequential	Du et al. (2017)	Text: Inflammation is one of the first responses of the immune system to infection. Stem: What is one of the first objections of the immune system to infection?
	Narayan et al. (2020)	Text: Former Beatle Sir Paul McCartney has topped the Sunday Times rich list of musicians with his £730 m fortune. Stem: Who is the richest musician in the world? Answer: Sir Paul McCartney
	Gao et al. (2018)	Text: The electric guitar is often emphasized, used with distortion and other effects, both as a rhythm instrument using repetitive riffs with a varying degree of complexity, and as a solo lead instrument. Stem: What is a solo lead instrument? Answer: The electric guitar

modeling and keyword extraction to explicitly model text that can be used as test items (Flor and Riordan, 2018; Gütl et al., 2011; Mazidi, 2017; Susanti et al., 2015). For instance, Flor and Riordan (2018) described a semantic-based AIG approach for generating factual test items using role labeling. Semantic role labeling is the process of assigning labels to different parts of a sentence in order to represent their semantic roles. Their system used the information gathered from role labeling with rule-based models to create *wh*-questions (e.g., what, who, where) and yes/no questions. Flor and Riordan (2018) used open language processing tools to analyze the grammatical structure of sentence parts required for assigning particular semantic roles. *SENNA*, for instance, is a popular tool for identifying generalizable core arguments in a sentence to provide specific labels, such as agent (or subject), patient (or object), location, and time of the event. Then, the system directly generated test items from the labeled sentences focusing on a focal label (e.g., agent) to select the most appropriate *wh*-question. Generating yes/no questions followed a similar logic. Examples of generated items using a semantic approach are shown in Table 2.

The third approach is sequence based. Sequential-based approaches are used to generate test items automatically using deep neural networks. Unlike the syntactic and semantic approaches, neural systems focus on generating test items by disambiguating and then learning the primary characteristics from the content in a corpus or knowledge base in order to generate test items without any manual feature engineering. This non-template-based AIG method does not identify the syntactic and semantic characteristics in the text. Instead, it attempts to learn from the test items that are used during training. Du, Shao, and Cardie (2017) described a sequential-based approach for generating reading comprehension items using a neural framework. Their system focused on mapping the problem statement and the reading passages to generate alternative questions to the problem statement using a recurrent neural network. Their system could generate various *wh*-questions (e.g., what, who, where). The generated items were then evaluated by SMEs to identify those items that were judged to be high in naturalness (e.g., grammatical and fluent) and difficulty (e.g., difficulty in syntactic divergence and reasoning). Narayan, Simoes, Ma, Craighead, and McDonald (2020) introduced a model focused on generating items that could be directly answered using the information from the reading passage. Their AIG approach used a transformer-based sequence-to-sequence model (Devlin et al., 2018). The system used the reading passages as input to generate the most suitable stem for the correct option. The model was based on publicly available question-answering databases (e.g., Rajpurkar et al., 2016). Gao, Bing, Chen, Lyu, and King (2018) described an approach for generating factual items from reading passages. Unlike the previous systems, Gao et al. controlled item difficulty in the generation process by using a sequence-to-sequence model that could use a sentence in the text that contained a corresponding answer with a specified difficulty level (e.g., "easy", "hard") to generate items. Examples of generated items using sequential approaches are shown in Table 2.

Evaluation of non-template-based AIG

The rapid advancement in non-template-based AIG offers a glimpse into the future of item development. This method not only overcomes a key limitation with template-based AIG but it also dramatically reduces the role of the SME in creating test items. Sequential neural network methods in particular, require no human input for engineering the features or identifying the set of

patterns or rules required to generate test items. Despite these potential benefits, the current applications of non-template-based AIG remains limited because they require a significant amount of training, instruction, and prior information that is very challenging to acquire. Most notably, all the approaches we describe for non-template-based AIG require a corpus or knowledge base. Moreover, the data in the corpus or knowledge base must be directly related to the purpose of the test because this information will be used to generate test items. When the content in the corpus is available, it can be structured using NLP methods defined at the syntactic, semantic, or sequential level to generate items. However, the data in corpora and knowledge bases that are currently available can only be used to produce very limited results that are characterized by items that are short (e.g., one or two-sentence) and simple. The quality of these simple items also varies across the approaches we described when evaluated by SMEs. The generated items are either overly simplistic or require heavy editing, filtering, and revisions to produce content that meets operational testing standard of quality. Conversely, when we evaluate the quality of the generated items using template-based AIG a markedly different result is reported. Gierl, Latifi et al. (2016) found that generated science test items were judged to be of equal or higher quality than items created by SMEs. In another study where a template-based AIG method was used to generate science items in English and Spanish, Gierl, Lai, Houston, Rich, and Boughton (2015) reported that 90% of the items were considered acceptable by SMEs while the remaining 10% required only minor revisions in order to meet an operational testing standard of quality.

Conclusion

AIG is a research area where cognitive and psychometric modeling practices guide the production of tests that include items generated with the aid of computer technology. AIG can be used to produce large numbers of high-quality test items required to support the current transition from paper to computer-based educational testing. Computer-based testing is one important form of educational technology that can be used to foster the development of a skilled workforce because computers allow educators to administer tests more frequently so students can receive continuous feedback as they develop their knowledge and skills. But when tests are administered more frequently using a computer, a large and continuous supply of new test items is needed. It is challenging—perhaps even impossible—to produce this large and continuous supply of new content using a traditional item development where SMEs author individual items. Hence, alternative item development methods are needed. Two general methods are currently available for producing large numbers of items using automated processes. The first method is template based. Template-based AIG can be characterized as a three-step approach where item modeling serves as the foundation. In the first step, content for the generated items is described by the SME. In the second step, the template for the content is created by the SME. In the third step, an algorithm places the Step 1 content into the Step 2 template using rules and constraints. Template-based AIG is a flexible approach that can be used to generate items for different levels in the education system, for a wide range of purposes, and different subject areas using a range of item formats and item types. The generated items are typically produced at a high standard of quality and therefore can be used directly in operational computer-based testing administrations. Because of the flexibility offered by this method and because the generated items meet high standards of quality, template-based AIG is currently the preferred method for generating items. But template-based AIG also relies on the SME's ability to create clearly structured cognitive and item models to guide the generation process. Not all content areas on educational tests permit explicit disambiguation and extraction of features. To address this limitation, a non-template-based AIG method can be used. Non-template-based AIG can be guided by the syntactic, semantic, or sequential structure of a text. These approaches all rely on a combination of natural language processing techniques and knowledge bases to generate statements, questions, and options from inputs such as texts, databases, and corpora of existing information without the need for templates. But to produce new items, a non-template-based AIG method requires large amounts of data specific to the educational testing area of interest. The data in the corpus must also be directly related to the purpose of the test because this information will be used to generate test items. Currently, corpora and knowledge bases are challenging to find and, even when they are available, produce limited results because the approaches used with non-template-based AIG generate short and simple test items that do not meet the standards of quality required for operational computer-based testing. Non-template AIG clearly holds tremendous promise for the future. But to meet our current item development challenges, template-based AIG is the method of choice for generating large numbers of items because it offers SMEs a great deal of control and flexibility for producing items in a wide range of content needed for computer-based testing.

Introduction

Much of what constitutes human progress is marked by the development of machines that perform what were formerly laborious manual tasks. Until recently the tasks best suited to mechanization were those that lacked a creative element, a domain once believed the exclusive province of human thought. On its surface, assembling test forms from pools of available items may seem more prosaic than artistic. Indeed, [Campion and Miller \(2006\)](#) characterize test forms as utilitarian objects whose form should follow their function. However, many would argue that test assembly, at least done properly, has always benefitted from a creative flair. And those who did it or saw it done years ago, when index cards representing each item were strewn about large tables and gradually, after much deliberation, organized into test forms, would certainly agree that considerable expert judgment was being exercised. However, the ongoing *software revolution* is now blurring the line between aesthetics and algorithms, with computers generating music, literature, and visual art ([McCormack and d’Inverno, 2012](#)). This chapter describes past and current efforts to apply algorithms that mechanize and so routinize the test assembly process. These algorithms are generally referred to as *automated test assembly* (ATA).

Test blueprints

Proper construction of almost anything begins with a blueprint, or an organized set of rules and instructions that govern the characteristics of the assembled object. Test forms are no exception. Blueprints that guide test assembly dictate the substantive, and ideally the statistical characteristics of the items that comprise a proper test form. A blueprint should be specific and detailed enough to ensure that all tests built to it measure the same traits in the same or equivalent ways ([Lane et al., 2016](#)).

Test specifications are usually based on a taxonomy that positions each item within the substantive domain that the test measures. For example, the taxonomy for a high-school level math test may include branches for arithmetic, algebra, geometry, and trigonometry items. Beneath each of these major classes, increasingly specific distinctions among items may be made. For example, algebra items might be classified as elementary or intermediate. Going further, an intermediate algebra item might be cataloged as dealing with exponents.

Specifications usually dictate the number of items that each test form should contain from each branch of the item taxonomy. The math test in our example might specify 15 items from the algebra branch, 10 from geometry, and 5 from trigonometry. These general requirements might be supplemented by rules that dictate the composition of the test at greater levels of detail. For example, the fifteen algebra items may need to include nine intermediate and six elementary items, with the nine intermediate items perhaps including two with exponents and seven without. The numbers of items required at a given level of specification may be fuzzy rather than absolute, representing indecision or indifference on the part of test developers. For example, a specification may call for between eight and ten intermediate algebra items rather than exactly nine.

Specifications at the lowest levels may be fuzzier still, dealt with by what can be viewed as akin to “randomization” in sampling or experimental design. Rather than demand that each form contain exactly two exponent items among the eight to ten intermediate algebra items, the specifications might restrict the number of such items to no more than two. Such a requirement does not insist that an exponent item be present on every form (since none is less than two). However, if exponent items are present they will not be so numerous as to dominate or bias what the form measures.

Test specifications can also dictate the statistical characteristics of a test form. Rules here can be expressed either in terms of classical item statistics (item difficulty and discrimination) or item response theory (IRT) information functions ([Davey and](#)

Hendrickson, 2010). Statistical goals might seek to fix the average difficulty or even the distribution of item difficulties across a form. IRT information functions characterize the measurement properties of a test more thoroughly, indicating where along the score scale the tests measures well or poorly.

Test assembly as a combinatorial optimization problem

The goal of test assembly is to select items from an available pool such that the blueprint specifications are uniformly satisfied. Although simple test construction problems can be and long have been solved by hand, more complex problems are good candidates for *combinatorial optimization* algorithms (Gill et al., 1982). These algorithms work to find combinations of items that maximize some desirable test property (the *objective function*) while at the same time satisfying the most important blueprint specifications (called *constraints*).

Theunissen (1985) developed the general approach to test construction as a combinatorial optimization problem and introduced linear and integer programming as a means of its solution. Stocking and Swanson (1993) were among the first to apply automated assembly in an operational setting. To do so they also introduced a heuristic called the *weighted deviations model* (WDM) as a means of finding approximate solutions to test assembly problems (Swanson and Stocking, 1993). Others have expanded the range of problems to which automated assembly can be applied, and the sophistication and practicality of the solution algorithms (van der Linden and Boekkooi-Timminga, 1989; van der Linden and Adema, 1997; van der Linden, 2005).

Blueprint specifications are generally divided between the objective and constraint sides of the optimization problem, the basic difference being that those assigned to the objective function are test characteristics that we would *like* to have, while those designated as constraints are *must* haves. Software packages differ in the way constraints and objective functions are defined, with a common arrangement having constraints dictate the substantive or content characteristics of the items that comprise an assembled test form while the objective function handles the statistical properties of the form. Typical choices of constraints and objective functions are described in the following sections.

Constraints

The substantive characteristics of each test item must be encoded into a series of classification variables or data fields. The content taxonomy for the test generally provides several of these fields, as for the sample item below:

Field	Value
Construct:	Math
Primary content:	Algebra
Secondary content:	Intermediate
Specific content:	Operations with exponents

Other substantive characteristics may also be encoded and considered during test assembly, including item type or format, whether the item stands alone or must appear in conjunction with other items (for example, a geometric figure on which several distinct items are jointly based), and cognitive level or depth of knowledge. Essentially, any item characteristic that is dictated or controlled by the test blueprint must be encoded as a data field.

The test blueprint is translated into constraints of two basic sorts: equality and inequality. Examples of both were briefly given above. An equality constraint requires a test form to contain a specific number of items of a given sort, e.g., the number of algebra items = 15. An inequality constraint requires that the number of items of a given sort be either less than or equal to, or greater than or equal to a given value, e.g., the number of algebra items ≤ 16 . Inequality constraints can be used singly to impose an upper bound on the number of items of a given sort allowed on a test, e.g., number of exponent items ≤ 2 . Pairing inequality constraints allows the number of algebra items to take on any value at or between given boundaries, e.g., the number of algebra items is ≥ 13 and the number of algebra items is ≤ 16 .

Objective functions

The objective function is commonly used to control the statistical or performance characteristics of test forms. It is defined as a real-valued function of the item performance statistics or values derived from those statistics. The goal of optimization is to minimize the objective function in some sense, subject to the constraints. Several examples are provided below to illustrate in a practical way how objective functions are used. Each example assumes that either classical or IRT performance statistics are available for all items in the assembly pool.

- (1) *Specifying average item difficulty.* This function sets the average item difficulty (e.g., proportion correct) equal to some specified value across the n items in a form. Let d_i be the difficulty for each item i in the pool, $i = 1, \dots, N$, where N is the number of items in the pool. Define a *selection variable* x_i such that $x_i = 1$ if item i is selected into the test form and 0 if not. Finally, let $\bar{d}$ be the

Fig. 1 Test characteristic curve.

average difficulty we would like a form to have. The objective function to be minimized is then the difference between the observed and targeted average item difficulty:

$$F = \bar{d} - \frac{1}{n} \sum_{i=1}^N x_i d_i \quad (1)$$

- (2) *Setting the test characteristic curve (TCC) of a form near to some target function.* The TCC is a function of IRT item parameter estimates. More specifically, the TCC is the sum of the *item characteristic curves* (ICCs) across the items in a test form. As shown in Fig. 1, the TCC is defined as a function relating examinee proficiency with expected test scores. As such it serves an important role in test equating, or the statistical adjustment of scores achieved on test forms that differ in difficulty in order that these scores be made directly comparable. Because equating works best when it's needed least, a common goal is to produce new test forms that are similar in difficulty to all preceding forms. Setting the TCC of a newly assembled test form as near as possible to some target function can accomplish this.

Let $p_i(t_j)$ be the value of the ICC for item i at proficiency level j . Under assumptions common to most IRT models, the TCC function at each proficiency level t_j is then the sum across the n items on the test form of the ICC values at that proficiency level. Suppose we have some target value for the TCC function, denoted as T_j across some grid of proficiency values $j = 1, \dots, J$. Then an objective function for selecting items that provide a close fit to this function can be written as:

$$F = \sum_{j=1}^J \sum_{i=1}^N x_i (p_i(t_j) - T_j)^2 \quad (2)$$

Although this function defines “close fit” in terms of squared errors, other definitions are possible (e.g., the sum of absolute distances between the observed TCC and the target). The function in Eq. (2) also weighs differences equally across all points of the proficiency scale. It is possible, and often sensible, to weight differences proportionally to the density of proficiency at each value j .

- (3) *Setting the test information function of a form close to some target.* The IRT information function characterizes the measurement properties of items and test forms (Lord, 1980). Information functions trace across the proficiency scale the measurement power items and forms contribute toward the estimation of test-taker proficiency. Fig. 2 shows example information functions for items that differ both in the amount of measurement power they possess and in where along the proficiency scale that power is most concentrated. Easier items, like Item 1, provide most of their measurement power at lower proficiency levels while more difficult items (like Item 2) measure most strongly at higher proficiency levels. Some items, like Item 3, provide little measurement power at any proficiency level.

Test information functions, like test characteristic curves, are additive across the items in a test form, again accepting assumptions common to most IRT models. Like item information functions, test information functions indicate the measurement power of a test form across the proficiency scale. Fig. 3 shows examples of easier and more difficult forms as well as forms that provide broader or more focused measurement.

Because they so concisely characterize the measurement properties of a test form, information functions are a common focus of the test assembly process. Given a test's measurement needs, target test information functions can be specified either judgmentally or empirically (e.g., by mimicking the information function of an effective, previously administered form). For example, the information functions in Fig. 3 might be set as targets for forms intended to prioritize measurement of either lower-performing test takers (*Easy*), or higher-performers (*Hard*). Similarly, the form labeled *Broad* would serve as a good target for a test intended to measure well across a broad swath of the proficiency range while the form labeled *Focused* is an effective target for a test intended to support a classification decision (e.g., pass or fail) at proficiency levels where measurement power is focused.

Fig. 2 Item information functions.

Fig. 3 Test information functions.

Test information can be incorporated into an assembly objective function exactly as a TCC in case (2) above. Let inf_{ij} be the item information function for item i evaluated at each of a grid of proficiency values $j = 1, \dots, J$. If the target information function across this same grid of proficiency values is again denoted as T_j , an objective function intended to meet this target as closely as possible is then:

$$F = \sum_{j=1}^J \sum_{i=1}^N x_i (inf_{ij} - T_j)^2 \quad (3)$$

The same considerations for use of this objective apply as above, namely that “close” can be defined by any distance metric and weights can be introduced to prioritize close fit at certain proficiency levels.

- (4) *Incorporating content considerations into the objective function.* It was noted above that the content properties of a test are often ensured through the constraint side of the optimization problem. However, doing so has both advantages and drawbacks. The advantage is that under most solution algorithms, satisfying constraints has a higher priority than optimizing the objective function, thereby reflecting the primacy of content in most assembly applications. The potential drawback is that some solution algorithms require that all constraints be met in order to return a solution. Otherwise, the problem is declared as *infeasible* (van der Linden, 2005).

Even if a feasible solution is found that meets all content constraints, the result may still be one that a human test assembler finds unappealing. An example is the case where a minor violation of the content requirements produces a significant improvement in the statistical properties of the form. A human test assembler might well prefer this tradeoff.

A better, or at least more transparent compromise between content and statistical properties might be struck by incorporating all or most of both into the objective function. This can be done by first defining some distance metric that compares the observed numbers of items in each content domain with the numbers required by the assembly blueprint.¹ Let o_k and r_k be the number of items observed and required in content domain $k = 1, 2, \dots, K$. Then let $f(o_k, r_k)$ be some function measuring

¹Considerable care must be taken both in the definition of distance metrics for content discrepancies and in the incorporation of both content and other objectives (e.g., test information) into a single objective function. The concern is that the things combined—either discrepancies across item types or content with other objectives—are not naturally on the same scale or even of the same order of magnitude. As such, the relative weighting of the various components of the objective function may not be explicit. A far more elegant solution than that presented here is to make use of solution algorithms that simultaneously optimize multiple objective functions (see Veldkamp, 1999).

the distance between observed and required values. Common choices for f are $(o_k - r_k)^2$ and $|o_k - r_k|$. It is also possible to have the difference function operate similarly to the inequality constraints discussed above, restricting the observed item counts to a permitted range rather than fixed to a single value. A disjunctive function like that below will do this:

$$f(o_k, r_k) = \begin{cases} (o_k - r_k^-)^2 & \text{if } o_k < r_k^- \\ 0 & \text{if } r_k^- \leq o_k \leq r_k^+ \\ (r_k^+ - o_k)^2 & \text{if } o_k > r_k^+ \end{cases} \quad (4)$$

where r_k^- and r_k^+ are the lower and upper boundaries of the range that should contain the observed number of items in domain k . The content contribution to the objective function is then:

$$\sum_{k=1}^K f(o_k, r_k), \quad (5)$$

to which can be added one (or several) of the statistical objectives in Eqs. (1)–(3) to complete the objective function.

Test developers may also judge that it is more important to meet some content requirements than others. These priorities can be reflected by assigning weight values, w_k , to each content domain, k in Eq. (5), resulting in the content contribution:

$$\sum_{k=1}^K w_k f(o_k, r_k). \quad (6)$$

Because both content and statistical requirements are represented in the objective function, it is further possible to assign a priority weight to each, making the compromise between content and statistical properties explicit.

- (5) *Practical objectives.* Practical considerations may impose requirements on test assembly beyond the content and statistical properties of test forms or item blocks. For example, when test security is a concern, requirements may stipulate that all items in the assembly pool be administered at roughly equal rates across a series of administration occasions. In this case, item usage rates need to be tracked and made available to the assembly routine, which would prioritize use in blocks currently under assembly of items that were more rarely used in prior assemblies.

Solution algorithms

Anyone who has assembled a test form by hand can attest to the difficulty of the problem. The task of identifying, accounting for, and choosing among a host of often competing priorities requires sharp judgment, endless patience, and steely determination. Translating the problem into a computerized algorithm has been equally difficult.

Test assembly belongs to a large class of combinatoric optimization problems referred to as *knapsack problems* (Fletcher, 2000). In its simplest form, the knapsack problem considers a set of objects, each of a certain size and carrying a given value. The problem is to select a subset of these objects that fit within a knapsack of given size such that their collective value is maximized. Test assembly generalizes this paradigm by typically imposing more than a single constraint; items are characterized by multiple content properties rather than a single weight. Such problems can always be solved by *brute force*, or by trying all possible combinations of objects (items, in our case). However, the number of possible item combinations (and so the computer processing time) grows at an alarming rate as the length of the test and, especially, the size of the assembly pool increase. For example, selecting a 40-item test from a modest 200-item pool results in a number of possible combinations that extends to 42 digits, rendering brute force an unworkable strategy for real-world problems. That leaves a series of algorithms of increasing sophistication that promise results that approximate the best (optimal) solution to increasing degree.

The first algorithms applied to operational test assembly problems were so-called *greedy heuristics*. Examples of these algorithms were developed by Swanson and Stocking (1993) and Luecht (1998). A greedy heuristic works by breaking the combinatoric problem down into bite-sized chunks, here the selection of a single item from the pool. The algorithm works to build the test from an item at a time, selecting at each point the “best” item from the remaining pool, given those items already selected. “Best” is usually defined in terms of the objective functions described under scenario (4), above, those that incorporate both content and statistical properties.

As a simple example, consider the item pool and test assembly requirements set out in the table below.

Classification	Items available in the pool	Items required on each form
Arithmetic	25	10
Algebra	50	5
Geometry	25	5
Total	100	20

The distribution of item content is seen to differ between what is available in the pool and what is required on the test form. Notably, Arithmetic items must comprise half of each test form but constitute only one-quarter of the pool. An effective heuristic algorithm will recognize this discrepancy and so prioritize Arithmetic items as early selections. Algebra items, in contrast, are over-represented in the pool relative to what is needed on each form. Selection of Algebra items can therefore wait until more immediate needs are met. Because these items are plentiful in the pool, they will likely be instrumental in meeting the statistical needs of the form.

Because heuristic algorithms proceed sequentially, they are subject to be trapped in *local* optima and so fail to minimize the objective function completely (Fletcher, 2000). A good heuristic will then attempt to adjust the completed form to further minimize the objective function (Swanson and Stocking, 1993). For example, a common strategy is to consider swapping each item currently selected within the test with each item remaining in the assembly pool. Trades that result in improvement are accepted and the process continues until no further improvement is possible.

Closer approximations to the optimal solution can be obtained through algorithms developed to solve general *integer programming* problems, of which our knapsack problem is a special case (Fletcher, 2000). These algorithms work to define and then divide the *solution space*, which in our case consists of all test forms that could possibly be assembled from the item pool and their associated objective function values. Strategies for doing so include the simplex method, branch-and-bound, and cutting-plane algorithms (Wolsey, 1998).

The *simplex method* was developed in the more general context of *linear programming*, of which integer programming is a special case (Katta, 1983). However, the method is applicable only in cases where the selection variable (x_i) is real-rather than integer-valued, meaning that items may contribute fractionally to a test form, clearly not a sensible result. Although such fractional values can be rounded to the nearest integer, doing so does not guarantee an optimal (or even feasible) solution. A better solution is found by applying a *branch-and-bound* or *cutting-plane* strategy to the rounded selection variables. These methods work to successively divide and constrain the problem space, ultimately converging on an optimal and integer-valued solution (Wolsey, 1998).

Branch-and-bound and cutting-plane algorithms are found in most modern integer programming software packages. Dozens of such packages are available, ranging in capabilities from limited to expansive, in complexity from simple to daunting, and in price from free to exorbitant. Performance of some of these packages is compared in Cor et al. (2008) and Luo (2020). Given the widespread availability of these packages and the speed of current computers, there is little reason to settle for a heuristic solution in most operational settings today.

Test assembly use cases

Although the discussion above is set in the context of assembling a single, conventional test form, ATA capabilities extend beyond this scenario. Most importantly, the assembled item collections need not constitute complete, intact test forms. Rather, they can be sets of items (often called *blocks* or *modules*) that serve as components of tests. Common use cases involving full test forms or item blocks are described below.

Simultaneous assembly of multiple forms or item blocks

Under this scenario, multiple test forms or item blocks are simultaneously assembled from a common item pool. Forms or blocks may be assembled to identical specifications or each may be unique. Sharing of items across forms or blocks may be prohibited or restricted to certain limits (e.g., no more than 10% of the items in a block may be shared with other blocks).² The trick under this scenario is to ensure that all forms or blocks meet specifications to a nearly equal degree. Heuristic algorithms often seek to ensure equality by selecting items for each form in turn rather than selecting an entire form and then moving on to the next, i.e., forms are selected in parallel rather than in series.

Adaptive test assembly

Under adaptive testing, different test takers receive different test forms, the difficulty of which is tailored by computer to the performance level of the test taker. Adaptive tests make a series of decisions as the test proceeds, selecting items or item blocks for administration based on the test-taker's demonstrated level of performance. Adaptive testing follows either of two basic strategies: *item-adaptive* and *multi-stage adaptive*, the difference being in the number of decision points and the size of the item block selected at each point. ATA has an important role to play under both strategies.

As conceived, item-adaptive tests select items individually, deciding what item to administer next based on the test-taker's performance on those items administered so far. A unique or nearly unique test form is then sequentially assembled for each test taker as the test proceeds. This assembly is entirely under control of the computer administering the test, with no human intervention possible. As such, item-adaptive testing was the object of much of the early research into automated test assembly. Stocking and Swanson (1993) developed their weighted deviations model heuristic, for use with adaptive testing systems. More recently, van

²Restricting sharing of items across forms can greatly increase the number of constraints imposed, and so the complexity of the assembly problem.

der Linden and others have applied the more formal integer programming algorithms described above to the same purpose (van der Linden and Reese, 1998).

Multi-stage testing is more constrained than item-adaptive, routing each test taker through a series of pre-assembled item blocks, with each block selected to be of a difficulty appropriate for the test-taker's performance level. Under this design, ATA is employed prior to rather than during test administration, assembling the collection of item blocks through which test takers are routed.

A particular sort of practical objective arises when data collected from administration of multiple test forms or adaptively selected blocks are expected to support IRT item calibration. In this case, assembly objectives may be added that ensure sufficient administration sample sizes for each item (Jewsbury and van Rijn, 2020).

As an adjunct to manual assembly

Apart from item-adaptive testing, where human inspection of test forms prior to administration is impossible, most applications of ATA involve human oversight of some sort. For example, test developers typically review and often revise test forms initially drafted by ATA. The advisability of this practice will be made clear in the section below detailing some of ATA's limitations. However, closer interaction between human and machine is possible, with both working cooperatively to produce a form. For example, a human test developer could manually assemble the core of a test form and then ask ATA to best complete it. ATA can also be used to suggest replacement items for those removed from a form under review. Modern item banking systems that include ATA capabilities typically allow for some level of interaction.

Limitations

The author has long recounted an anecdote wherein he used an early ATA system to assemble what he naively believed to be a "perfect" test form measuring high-school level science. He proudly delivered this form to the test development team expecting fulsome praise. However, the test developers instead noted that the form contained an item pertaining to lake-effect snow, another concerning stream ecology and a third dealing with ocean currents. "There is", they declared, "an awful lot of water on this form". There was, of course, no formal content requirement that dealt with water level. Rather, an excess of watery content is simply one of those things that a good, experienced test developer recognizes when one sees it.

Liquid is in fact one of thousands of such things that don't rise to the level of requiring a formal requirement being encoded and enforced. These things instead fall under the realm of learned experience and expert judgment. Therein lies the primary limitation of ATA: the system can attend to only those test characteristics that are explicitly identified and called out, and these characteristics will always be a fraction of those that test developers might deem important. Of course, it is ever a matter of debate as to the extent that these characteristics impact test-taker performance and so warrant attention.

Human review of computer-generated forms is the principal way of dealing with the limitations of ATA systems. However, there are situations where review is not possible and ATA, and the inputs it's provided, need to be trusted more completely. Chief among these situations is item-adaptive testing, where test forms are assembled uniquely for each test taker in real time as the test proceeds. Where review is not possible, it seems prudent to constrain test assembly more strictly and at greater levels of detail than would be necessary for human assembly (Davey et al., 2016).

One of the primary benefits of human review is the identification of item "enemies". These are pairs or larger combinations of items that for any of a variety of reasons should not appear together on a form. They may cue one another, contradict one another, or be too similar in content or appearance. The three water-based items discussed above fall into this last category. Although item enemies can be identified and coded as such prior to assembly, this becomes a daunting and ultimately impossible task as the size of an item pool (or the number of factors that render items as enemies) increases.

A final limitation pertains to test assembly generally but seems more salient under ATA. This is that item characteristics are often poorly determined meaning that efforts to constrain them are necessarily murky. This is most obvious in the case of IRT item parameter estimates which often contain substantial error, meaning that test characteristic curves or information functions used as objectives may be poorly estimated. The impact of this is most pronounced in the case where the objective function is to maximize test information. This will likely result in the selection of items whose information functions have been over-estimated, meaning the resulting test information function will be grossly over-estimated.

Even item content classifications are sometimes imprecise, with test developers often disagreeing as to how an item should be classified. What it means to "optimize" test characteristics given uncertainty in both item content and statistical properties is a question to ponder. At the very least, it may mean that there may be little practical difference between solutions returned by simpler heuristic algorithms and the "more optimal" solutions returned by more complex algorithms.

Conclusion

Most technologies move over time from being complex, expensive, and specialized to being simple, cheap, and widely accessible. This has certainly been true of automated test assembly, which is now available to all testing programs through a variety of convenient and inexpensive software systems.

ATA can make test assembly much easier and far more efficient than manual procedures. However, it requires time and attention up front to define the assembly problem and create the system inputs needed to solve it. As such, the capability is best applied by testing programs that assemble test forms routinely, to the same or similar requirements.

Finally, it is best in nearly all cases that human test developers be as closely involved in the assembly process as possible, either in a review and oversight capacity or interacting with the ATA system throughout the assembly process in complete cooperation. “Trust, but verify” ever has been and ever will be a useful motto to live by.

Introduction

Tests are an important type of quantitative measurement instruments. They are used to measure one or more constructs of interest. Most tests use a fixed set of test items and the test items are presented in a fixed order. Computerized adaptive tests differ from this in that the set of items presented to the examinee is based on the examinee's responses to previous items in the same test and can make use of existing preknowledge about the standing of the individual regarding the construct of interest. Computerized adaptive testing (CAT) is typically based on psychometric item response theory models (IRT; van der Linden, 2016a) and comprises six essential building blocks.

The history of IRT-based CAT dates back to the 1970s. Although individual attempts had already been made to develop response-dependent test procedures before then (see Chang, 2015 and Weiss, 2004 for overviews), it was only from this time on that viable CAT concepts were formulated and tested. With their groundbreaking work, Lord (1980) and Weiss (1983) were the first to present the essential aspects of adaptive testing in an integrated form. Starting in the 1980s, numerous fundamental questions relevant for an operational application of CAT were investigated in the development of the Computerized Adaptive Testing version of the Armed Services Vocational Aptitude Battery (CAT-ASVAB; Sands et al., 1997). Since then, the US military has been using that test battery for personnel selection with approximately 400,000 test takers per year. In addition, CAT applications can also be found in a wide range of areas such as health measurement, competence measurement (e.g., in large-scale assessments of student achievement), intelligence testing, aptitude testing, and testing in higher education.

In this article I will first describe the basic idea of CAT. In order to configure a modern CAT-system, six building blocks need to be specified. I will describe the basic methods used in each of these building blocks. I will thereby clarify that multistage testing (MST) is a special kind of adaptive testing. Next, I will summarize the current state of knowledge about the effects of CAT on (a) measurement efficiency, (b) the validity of test score interpretations, and (c) test-taking motivation. I will end the article with a conclusion, an overview of current research directions in the area of CAT, and a brief outlook.

How computerized adaptive testing works

The flowchart shown in Fig. 1 shows the general principle behind CAT. The test starts with the selection and presentation of an initial item, which is drawn from an existing item pool (Building blocks 1 and 2; see **Item pool** and **Start of the test** sections). The response given to this item is recorded and scored. With this empirical information a little bit more is known than before about the level of the examinee regarding the construct to be measured. This information is used to derive a provisional estimate $\hat{\theta}$ of the person parameter, that is, the examinee's score on the construct of interest (Building block 3; see **Person parameter estimation** section). After this, it is checked whether one or more previously defined termination criteria are fulfilled. After the first

Fig. 1 Flowchart of the core principles of computerized adaptive testing.

item, this will normally not be the case. Therefore, Steps 1 to 3 are iterated until all termination criteria are met. The selection of one (fully adaptive CAT) or more items (MST, testlet-based CAT) in Step 1 uses the responses that the examinee has given in previous iterations. Note that, to achieve good readability, the rest of the text refers to the selection of individual items. This includes the possibility of selecting groups of items (testlets or modules in MST), even if this is not explicitly added each time. The previous responses are used in Step 1 to be able to present only those items that fit well to the examinee with regard to an optimality criterion (Building block 4; see [Item selection](#) section). The item with the maximum value of this optimality criterion is presented next. For most optimality criteria used in CAT, examinees with high levels regarding the construct of interest answer more difficult items than examinees with lower levels; this fosters the precision of the measurement (see [Measurement efficiency](#) section). In addition to this, adaptive item selection also avoids the situation that examinees with a high level regarding the construct being measured (e.g., high ability level) have to answer items that are much too easy for them and that examinees with a low level have to answer items that are much too difficult for them. This tailored item presentation was traditionally expected to foster the test-taking motivation of the examinees. Empirical results on whether this expectation is met in operational testing will be discussed in [Test-taking motivation](#) section. In addition to the statistical optimality criterion, other nonstatistical constraints (Building block 5; see [Constraint management](#) section) are usually taken into account during item selection in Step 1. After all of the termination criteria have been met, the final person parameter estimate $\hat{\theta}$ is determined and the test is terminated (Building block 6; see [End of the test](#) section).

Building blocks

Item pool

The item pool is the complete set of items that can be used for testing. Over the course of an adaptive test, the item that meets the optimality criterion best is selected from the remaining eligible items in the item pool. To calculate the optimality criteria typically employed in CAT, statistical properties are required for all items in the item pool. These statistical properties are estimated using IRT models from responses gathered in a calibration study. Many adaptive tests use logistic IRT models with one (1PL), two (2PL), or three (3PL) item parameters, where the item parameters represent these item properties. The 3PL is the most general of these three models. This model defines the probability of a correct response $u_{ij} = 1$ of person $j = 1, \dots, N$ with latent ability θ_j to an item $i = 1, \dots, I$ as:

$$P(u_{ij} = 1 | \theta_j, a_i, b_i, c_i) = c_i + (1 - c_i) \frac{\exp[a_i(\theta_j - b_i)]}{1 + \exp[a_i(\theta_j - b_i)]} \quad (1)$$

where a_i is the discrimination parameter, b_i is the difficulty parameter, and c_i is the pseudo-guessing parameter of item i . [Eq. \(1\)](#) reduces to the 2PL when c_i is set to zero for all items, which in turn reduces to the 1PL when a_i is set to a constant ([van der Linden, 2016a](#)). The use of IRT models is beneficial in CAT because the item difficulties and the persons are located on the same common scale. Thereby, examinees can be compared with each other even if they have answered different items. Based on their responses, they can be placed between the items and thus on the common scale that represents the levels of the construct of interest.

For typical adaptive tests, the item parameters are estimated in the calibration phase and then considered as known in the operational CAT phase in which the test is used to test examinees. Therefore, the calibration study is of utmost importance to ensure that an adaptive test functions properly. In order to obtain precise item parameter estimates, relatively large calibration samples are needed. As a rough rule of thumb, [de Ayala \(2009\)](#) recommends a minimum of a few hundred responses per item for the 1PL

model, 500 responses for the 2PL model, and 1000 responses for the 3PL model under good conditions (good fit between item difficulties and ability distribution, many items per examinee). Online calibration methods provide possibilities to reduce these relatively large demands regarding the sample size in the CAT construction phase. The Continuous Calibration Strategy (CCS) by Fink et al. (2018), for example, allows the complete calibration to be carried out while the test is already in use.

Start of the test

At the beginning of an adaptive test, no responses are available yet, which means that the selection of the first item cannot be informed by previously given responses. Frequently, the first item is therefore drawn randomly from a set of “icebreaker” items, which have a low item difficulty. Alternative procedures are to make completely random draws from the item pool or to use information from previous tests (if available) to select the first item. However, both simulations and empirical studies have shown that, in CAT, the selection of the first item has a comparatively small influence on the precision of the final test results. Accordingly, most authors assign only minor importance to the choice of the first item in CAT (e.g., Hambleton et al., 1991).

Person parameter estimation

In CAT, provisional estimates for the person parameters are derived in Step 3 and final estimates in Step 4 (see Fig. 1). Common IRT estimation methods (van der Linden, 2016b) can be used for the estimation of the person parameters. Both maximum likelihood (ML) estimators, which include the WLE (Weighted Likelihood Estimate; Warm, 1989), as well as Bayesian estimators such as the EAP (Expected a Posteriori; Bock and Mislevy, 1982) or the BME (Bayes Modal Estimate; Mislevy, 1986) are frequently used in CAT. For unidimensional CAT, comparisons of different person parameter estimation methods can be found in van der Linden and Pashley (2010) and Cheng and Liou (2000). Because ML estimators are undefined for invariant response patterns (i.e., if only correct or only incorrect answers have been given), in practice, the provisional person parameter estimate $\hat{\theta}$ is often derived with Bayesian estimators until correct and incorrect answers are recorded and then an ML-based estimator is used.

Item selection

In prototypical CAT, item selection is accomplished on the level of single items; this is also referred to as fully adaptive item selection (Weiss, 2011). However, there are also approaches with limited adaptivity in which groups of items are selected jointly. This section describes both approaches successively.

Fully adaptive item selection

Adaptation at the item level offers the most flexible way of adapting the presented items to the examinee’s response behavior. The adaptation is based on an optimality criterion that is calculated after each response for all eligible items in the item pool. The item with the most desirable value of this optimality criterion is then selected for presentation. A frequently used optimality criterion is maximum item information given $\hat{\theta}$. The calculation of the item information varies with respect to the IRT model used. For the 3PL model, the item information function is given by:

$$I_i(\theta) = a_i^2 \left(\frac{p_i(\theta) - c_i}{1 - c_i} \right)^2 \frac{q_i(\theta)}{p_i(\theta)} \quad (2)$$

where $p_i(\theta)$ is the probability that an examinee with ability θ can solve item i (see Eq. 1) and $q_i(\theta)$ is the probability that item i cannot be solved by this examinee, so that $q_i(\theta) = 1 - p_i(\theta)$ applies. The equation shows that the discrimination parameter a_i as well as the pseudo-guessing parameter c_i have a direct influence on the item information $I_i(\theta)$. While high a -parameters are associated with high item information, high c -parameters are associated with low item information. With regard to the c -parameter, the highest item information results for $c_i = 0$.

The 2PL model and the 1PL model have fewer item parameters than the 3PL model. Therefore, the equation for the item information for the 2PL is reduced to:

$$I_i(\theta) = a_i^2 p_i(\theta) q_i(\theta) \quad (3)$$

and for the 1PL to:

$$I_i(\theta) = p_i(\theta) q_i(\theta) \quad (4)$$

Thus, in item selection that is conducted according to the maximum item information criterion, parameters a and c are relevant in the 3PL and a is relevant in the 2PL. In the 1PL, neither a nor c appears in the item information function. In this IRT model, the maximum value for I_i is achieved if $p_i(\theta) = q_i(\theta) = 0.5$, which is the case if the item difficulty is equal to the provisional person parameter estimate $\hat{\theta}$. Item selection that uses the maximum item information criterion therefore selects the item whose item difficulty is closest to $\hat{\theta}$.

Note that, because the standard error of the person parameter estimate can be represented by $SE(\theta) = 1/\sqrt{I(\theta)}$ for the 1PL and the 2PL, applying the maximum item information criterion means reducing the SE in the best possible way each time an item is selected if these models are used.

An overview of alternative optimality criteria for CAT item selection can be found, for example, in [van der Linden and Pashley \(2010\)](#). In some testing situations, these alternative optimality criteria can be used to increase the performance of CAT compared to the performance achieved with item selection conducted according to the maximum item information criterion. However, the maximum item information criterion has been proved to be only slightly worse in these cases and is applicable across a wide range of situations. Therefore, this robust criterion is considered the standard criterion for item selection in CAT.

Item selection with limited adaptivity

In some studies, such as large-scale assessments of student achievement (e.g., PISA, PIRLS, or TIMSS), items are grouped into testlets. Testlets consist of several items that refer to a common stimulus and should be presented as a whole. Solutions for the adaptive selection of complete testlets instead of single items while considering the local dependence of the items which share the same stimulus have been proposed by [Keng \(2011\)](#) for unidimensional CAT and by [Frey et al. \(2016\)](#) for multidimensional CAT.

Another type of tests from the early days of CAT that use observed response behavior for item selection purposes have recently experienced a renaissance. These type of tests are tests with two to five stages (multistage tests; e.g., [Yan et al., 2014](#); initially referred to as flexilevel tests, [Lord, 1971](#)). Multistage testing (MST) has probably come back into focus because—at first glance—organizational requirements of LSAs can be solved well with it. Each stage of a multistage test consists of several items and the stages are assembled in advance. In MST, examinees initially answer the items included in a “routing test” ([Lord, 1971, 1980](#)). Examinees who do well in this routing test (i.e., give many correct answers) get a harder subtest (called module) and examinees who do not do so well in the routing test (i.e., give many incorrect answers) get an easier subtest in the next stage. This principle is followed for all stages of the test. [Fig. 2](#) shows a sample MST design with a routing test in stage 1, three modules with different average difficulty in stages 2 and 3 each.

MST also incorporates an adaptation even though it is relatively unrefined compared to fully adaptive item selection on the level of single items. Therefore, MST represents an intermediate stage between nonadaptive and fully adaptive computerized testing that does not make use of the full potential of CAT. The fact that all possible paths are known a-priori in MST is sometimes mentioned as an advantage compared to fully adaptive item selection. With all paths known, it is straightforward to plan the exposure rates of items and to ensure that individual test takers are confronted with certain proportions of items per facet of the measured construct (e.g., subdimensions). However, this is not fully convincing, as such test properties can also be achieved (and often even more precise) through constraint management methods (see [Constraint management](#) section) in fully adaptive item selection. Detailed information on MST can be found in [Magis et al. \(2017\)](#) and [Yan et al. \(2014\)](#).

Constraint management

Adaptive item selection is based on a statistical optimality criterion (see [Item selection](#) section). However, in practical CAT applications, additional nonstatistical requirements usually have to be met. These typically mean selecting items that are not optimal in a statistical sense. In such a case, a compromise between meeting statistical optimality and nonstatistical requirements is necessary. The methods used to consider nonstatistical requirements in CAT are subsumed under the term constraint management methods. These methods can be divided into two groups. The first group of constraint management methods controls how often individual items are presented across examinees and is called exposure control. The second group of methods regulates the handling of content requirements for each examinee and is referred to as content management.

Fig. 2 1-3-Multistage testing design with one routing test, three modules with differing average difficulty at stage 2 and three modules with differing average difficulty at stage 3.

Exposure control methods are often necessary in CAT because item selection that aims to optimize only the statistical optimality can easily lead to situations in which some items are presented to many or even all examinees while other items are rarely or never presented. This can lead to test security issues because frequently presented items have an increased probability of becoming publicly known in the population of future test takers. In this case, the item parameter estimates from the calibration study (with examinees without item preknowledge) can become invalid. Various exposure control strategies have been developed in order to control the frequency with which items are presented. The simple Randomesque Method suggested by [Kingsbury and Zara \(1989\)](#) consists of adding a stochastic component to the statistical optimality criterion. Instead of selecting the single best item according to the optimality criterion, a random draw from the m optimal items is carried out; with m typically being a number between 4 and 10. The Randomesque Method does not guarantee that the maximum item exposure rate is limited to a target rate, but it can prevent the same item from being used repeatedly for examinees with similar levels of the construct to be measured. A more thorough control of item exposure rates can be achieved with more elaborate algorithms such as the Sympson-Hetter Method ([Sympson and Hetter, 1985](#)), the Progressive Method ([Revuelta and Ponsoda, 1998](#)), and the Alpha Stratification Method ([Cheng et al., 2009](#)). A comparison of the performance achieved with the difference exposure control methods can be found in [Leroux et al. \(2013\)](#).

In addition to controlling item exposure rates across examinees, it is often desirable to control the type of items presented to the individual examinees. Such methods are referred to as content management methods. They can be used to control the proportions of items presented per facet of the construct of interest, per response format, per position of the correct answer, and others. Modern content management methods make it possible to consider several of these requirements simultaneously. Probably, the most powerful content management method is the Shadow Testing Method proposed by [van der Linden and Reese \(1998\)](#). With this method, very good results are achieved even for high numbers of nonstatistical constraints. Heuristic methods such as the Weighted Deviation Model ([Stocking and Swanson, 1993](#)), the Weighted Penalty Model ([Shin et al., 2009](#)), and the Maximum Priority Index Method ([Cheng and Chang, 2009](#)) represent alternatives to the Shadow Testing Method for many situations. They are easy to implement and perform well, even though they might not be the best choice for highly constrained testing situations. Comparisons of the heuristic content balancing methods can be found in [Born and Frey \(2017\)](#) and [He et al. \(2014\)](#).

End of the test

An adaptive test is continued until one or more predefined test termination criteria are met. Four frequently used test termination criteria are listed below ([Linacre, 2000](#)).

An adaptive test is terminated when

1. a specified number of items has been answered and/or
2. the standard error of the person parameter estimate is sufficiently small and/or
3. the maximum testing time is reached and/or
4. the complete item pool has been presented.

[Segall \(2005\)](#) points out that the choice of the termination criterion strongly depends on the context, the item pool, and the testing conditions. If, on the one hand, the test scores are to be used for decisions that have a high personal relevance (e.g., university admission tests), person parameter estimates that have comparable precision across examinees are desirable, as they result from the second test termination criterion. If, on the other hand, complete groups of examinees are tested at the same time (e.g., complete school classes), tests with varying test lengths are impractical or even not feasible. In such conditions, adaptive tests are usually terminated for all members of the tested group after a fixed time has elapsed (test termination Criterion 3). Because data stemming from such studies is typically analyzed with group-level statistics, varying precision between examinees plays a minor role here.

In practice, a combination of test termination criteria is often used. A simulation study can be found in [Babcock and Weiss \(2012\)](#), where different test termination criteria as well as combinations of them were examined while taking item-pool characteristics into account.

Effects of adaptive testing

Because CAT is linked to the use of a computer, it has the same advantages and disadvantages as computer-based testing (CBT). This is solely due to the use of a computer to administer the test and is not connected to the use of adaptive test algorithms. Because these advantages and disadvantages have been intensively discussed before (e.g., [Parshall et al., 2002](#)), they are only briefly summarized here. The advantages that can be achieved with CBT compared to paper-and-pencil testing include high test security, highly standardized testing procedures, quick and accurate determination of test results, application without psychometric expertise, fast reporting of test results, and the possibility of using innovative item formats (e.g., [Sireci and Zenisky, 2016](#)). The potential disadvantages of CBT compared to paper-and-pencil testing are less of a conceptual and more of an organizational nature. They include higher test development effort, expenses incurred by providing computers at the testing location, and potential fairness issues caused by individual differences in computer-related personality variables (e.g., familiarity with computers, computer anxiety) that may be correlated with the construct of interest.

Measurement efficiency

The main advantage of CAT compared to nonadaptive testing is its superiority in terms of measurement efficiency. The measurement efficiency of a test can be conceptualized as the ratio of measurement precision to test length (Segall, 2005). The test length is usually quantified by the number of items presented. Measurement precision is defined as the accuracy of the test scores. It can vary with respect to θ in IRT modeling. One way to represent it is with the test information function. If a single value for a test's measurement efficiency is of interest, the average test information can be calculated for a defined theta range and divided by the average number of items presented.

Item selection in CAT is often based on the criterion of maximum item information (see **Fully adaptive item selection** section). This maximizes the measurement precision and thus the measurement efficiency. This is connected to two advantages of CAT. Firstly, the number of items needed in CAT to reach the same measurement precision as in nonadaptive testing is much lower than the number needed in nonadaptive testing (typically only 40%–60% of the items). Secondly, CAT can align the standard errors of the person parameter estimates across examinees, especially if a corresponding test termination criterion such as Criterion 2 (see **End of the test** section) is used. The degree of the alignment of the standard errors across examinees that can be reached also depends on the characteristics of the item pool. To achieve perfectly equal standard errors for all examinees, the item pool needs to include enough items for the θ -value of each examinee. This means that the test information function of the item pool must exceed a certain level across the entire θ -range for which examinees are expected. If this information function falls below this level for a certain θ -range, suboptimal items will be selected for examinees in this range and this will result in higher standard errors of the final person parameter estimates.

Validity

According to the Standards for Educational and Psychological Testing (AERA et al., 2014, p. 11), validity “refers to the degree to which evidence and theory support the interpretations of test scores for proposed uses of tests”. In empirical validation studies, it is common practice to clarify, among other aspects, whether test results (a) are correlated as expected with other measures representing the same construct (convergent evidence) and (b) are uncorrelated with measures representing theoretically unrelated constructs (discriminant evidence).

With regard to convergent validity evidence (a), CAT results in higher correlations with convergent variables than nonadaptive testing if its superior measurement efficiency is utilized for an increase in measurement precision. This is the case because the increased measurement precision means an increase in the proportion of systematic variance of the person parameter estimates that is due to the construct that the test aims to measure in relation to unsystematic error variance (Frey, 2006). The additional systematic variance is likely to correlate with convergent variables, while the unsystematic error variance has a zero correlation as expectancy with all variables by definition. The result is a higher correlation with convergent variables. If, however, CAT's superior measurement efficiency is used to reduce the number of items presented while maintaining the same measurement precision as in a nonadaptive test, it is reasonable to expect no effects on the convergent validity evidence.

While the effects of CAT on convergent validity evidence can be derived directly from the optimality criterion used for adaptive item selection, the effects of CAT on discriminant validity evidence are somewhat more difficult to predict. By increasing the proportion of systematic variance to the total variance of the estimated person parameters, no systematic changes in the correlation of the test score with discriminant variables are to be expected. This is the case because both the systematic variance and the unsystematic error variance are expected to be uncorrelated with discriminant variables. Increasing the proportion of systematic variance will thus not affect the correlation with discriminant variables. Nevertheless, the special type of testing that is realized in CAT obviously can have an effect on psychological variables, which may in turn interfere with the test results. For example, the fact that only about half of the items are answered correctly may lead to negative emotional reactions such as anxiety or anger, especially in highly proficient examinees who are not used to failing in such a large proportion of test items. These negative emotions can then have a (typically negative) impact on the test scores. However, the goal of most achievement tests is to measure maximum individual performance. If the test results are lowered by confounding variables such as anxiety or anger, they do not represent maximum performance. This will limit or may even jeopardize the validity of test score interpretations. In order to derive valid test score interpretations, near-zero correlations between test scores and confounding variables are thus aimed for and considered to provide discriminant validity evidence. Empirical results presented in Frey (2006) in fact showed near-zero correlations between confounding variables (such as trait test anxiety and state anger) measured before the test and negative affect measured during the test for the adaptive version of a test and significant correlations for a nonadaptive version of the same test. However, this does not mean that CAT generally increases discriminant validity. Ortner and Caspers (2011) reported opposite effects for their study with $N = 110$ university students: Significant correlations between the confounding variable trait test anxiety and intelligence as the construct of interest were found in CAT but not in nonadaptive testing. However, the problematic correlations observed for CAT disappeared in this study when the test instruction included information about the adaptivity and the fact that the proportion of items that can be solved was around 50% for all examinees. Thus, transparent test instruction is important in CAT with regard to the discriminant validity of the test score interpretations.

Test-taking motivation

Previous research has repeatedly claimed that CAT has a positive effect on test-taking motivation. This claim can be traced back to early works on CAT by [Betz \(1975\)](#) and [Betz and Weiss \(1976a,b\)](#). On the basis of the results of several experiments, [Betz and Weiss \(1976b\)](#) concluded that CAT increases test-taking motivation, especially for examinees with low proficiency. This finding was explained by the fact that examinees get test items whose item difficulty is tailored to their proficiency level. CAT prevents examinees from being presented both with items that are much too easy for them and hence may cause boredom and with items that are much too difficult for them and hence may cause frustration. Beyond these early findings, however, empirical evidence that supports the positive effects of CAT on test-taking motivation is sparse ([Wise, 2014](#)).

Several studies from the 1990s and 2000s even point in the opposite direction, indicating a negative effect of CAT on test-taking motivation. Those studies frequently argue that presenting items with an average probability of a correct response of .50 in CAT does not lead to high test-taking motivation (e.g., [Bergstrom et al., 1992](#); [Eggen, 2004](#); [Ponsoda et al., 1999](#)). Such a test is considered to be demotivating, especially for high-performing examinees who are used to being able to solve a much larger proportion of test items. This argument is supported by the results of [Ortner et al. \(2014\)](#). They compared an adaptive and a nonadaptive version of a nonverbal matrices test with regard to the two motivational aspects of situational fear of failure and perceived probability of success in the test. The examinees in the adaptive condition reported higher fear of failure and lower perceived probability of success compared to the examinees in the nonadaptive condition.

The expectancy-value model of test-taking motivation proposed by [Asseburg \(2011\)](#) unites these seemingly contradicting results regarding the effects of CAT on test-taking motivation by considering the expectation and value components separately. The model was examined in a comprehensive experiment with $N = 703$ students in Grade 9. The findings of the Asseburg study are manifold and lead to differentiated practical recommendations for the configuration of computerized adaptive tests for different test settings and groups of test takers. One conclusion of the study concerns the test instruction. If the test instructions explain the adaptivity to the examinees, as well as the fact that a probability of .50 for correct answers is normal in CAT, unwanted effects on test-taking motivation can be avoided.

Another important point with regard to the motivational effects of CAT is connected with the average difficulty of the items presented. If an optimality criterion is used for item selection that leads to an average proportion of correct answers of about 70%, the resulting test-taking motivation is substantially higher compared to a typical CAT with a proportion of around 50% correct answers ([Ling et al., 2017](#)) even though this is connected to a somewhat lower measurement efficiency. In conclusion, there is no straightforward answer to the question of whether CAT fosters test-taking motivation or not. Nonetheless, the way in which CAT needs to be specified in order for a given test situation to have positive motivational effects is clearly documented.

Conclusion

CAT is a special way of testing that uses the examinees' responses to present only statistically optimal items while taking nonstatistical constraints into account. CAT is made up of six building blocks: item pool, start of the test, person parameter estimation, item selection, constraint management, and end of the test. A collection of methods is used to specify these building blocks. If these methods are configured in such a way that they fit well to a given assessment situation, the use of CAT can be expected to have positive effects on measurement efficiency and on the validity of test score interpretations while also avoiding negative effects on test-taking motivation. In addition to the basic aspects of CAT that are summarized in this article, CAT-related research covers many additional areas. Several of these are concerned with expanding the application range of CAT to novel testing situations and to complex requirements regarding the type of measures to be obtained. Such requirements involve, for example, incorporating more complex IRT models, such as compensatory multidimensional models ([Frey and Seitz, 2009](#)), noncompensatory multidimensional models ([Hsu and Wang, 2019](#)), or higher-order models ([Wang and Kingston, 2019](#)). Another line of research focuses on the possibility of using CAT in order to overcome general measurement and testing problems, for example, to use the available testing time optimally by using the maximum information per time unit as the item selection criterion ([Cheng et al., 2017](#)) or to control for item position effects ([Frey and Fink, in press](#)).

As the transition from paper-based to computer-based testing will certainly not stop, it is most likely that CAT will play an even greater role in the future than it does now. CAT is not only able to realize highly efficient measurements; it can also consider an enormous number of constraints automatically and can thereby help to make tests better and to reduce costs. These features make CAT especially attractive for large and complex assessments such as large-scale assessments of student achievement ([Frey and Seitz, 2011](#)). In the future, the trend might go to CAT as novel, self-optimizing testing systems in which procedures that are now carried out sequentially, such as item calibration, fit analysis, drift and cheating detection, and test score reporting, are represented by continuous processes.

Tests or assessments play a major role in education. Their main purpose is to gain insights into the test taker's knowledge, skills, and abilities (KSAs) on the focal content measured by the test. These insights have to be communicated to various stakeholders or users (e.g., teachers, principals, administrators, admissions officers, parents, and often the test-takers themselves) using some form of a score report. Score reports, which include both static (paper/online) reports and interactive dashboards, are the vehicles used to communicate results of the assessment to score users. These results are often communicated through graphical representations and data tables for individual students or groups of test takers (Hambleton and Zenisky, 2013). To be useful, however, score reports should convey the results from the assessment in a manner that makes it easy for score users to make clear interpretations about the test taker's KSAs as measured on the test and use those test results to take appropriate actions that are warranted based on the test's purpose. In fact, a test's validity is dependent on the extent to which inferences drawn from the test results are appropriate and meaningful for the intended stakeholders (Hubley and Zumbo, 2011; Kane, 2006, 2013; Tannenbaum, 2019; Zapata-Rivera and Katz, 2014). Some authors (e.g., O'Leary et al., 2017) have even suggested that the evidence of interpretability of the information contained in score reports should be included as one of the sources of a test's validity evidence. Therefore, it is critical that score reports are appropriately designed for specific audiences and presented in simple and clear language to enable score users to interpret the information accurately and use the results appropriately.

In this chapter, I first broadly discuss the development of score reporting research with a particular focus on two broad areas: (i) audience specificity and (ii) stakeholder interpretation and use of information presented in score reports. Then, I introduce the iterative multistep framework for the design and evaluation of score reports. Within this framework, I focus on recommended evaluation methods that would provide practitioners with the necessary tools to help with the implementation of this iterative multistep framework. I conclude the chapter by suggesting areas for future research, particularly surrounding the design and development of interactive reporting systems.

Score reporting research

Score reporting, as a field, goes beyond just communicating the scores obtained on a test. Zapata-Rivera and Katz (2014) rightly point out that score reports are "where the rubber hits the road" (p. 442) in the validity argument for a test. For some stakeholders, such as parents, score reports are the first, and perhaps only, point of interaction with the assessment and its results—therefore, score reports should not only communicate scores from the assessment, but also serve as the vehicle for communicating information about the test's purpose, convey the meaning of various scores, sub-domain scores, and any performance levels, and serve as a resource for actionable next steps for the intended stakeholder. In other words, an ideal score report would be designed to serve as a comprehensive one-stop shop to communicate the test's purpose, the intended interpretations from the scores, and the suggested next steps to the score user. As Hambleton and Zenisky (2013) point out, "good reporting" (p. 481) should be contextualized

and provide intended stakeholders with results that are meaningful and practical by linking them to actions. And, as previously mentioned, the validity of the assessment is dependent upon the appropriate and accurate inferences drawn from score reports by stakeholders.

However, until about 10 years ago, score reporting was by far the most under-researched area within educational measurement (Hambleton and Zenisky, 2013). This was because score reporting was historically not conducted as a planned activity during test development, but more as an “ad hoc activity” (p. 480) at the end of the test development process (Hambleton and Zenisky, 2013). Over the last couple of decades this has been changing. Following some ground-breaking work by Howard Wainer around the inaccessibility of data presentation formats (e.g., Wainer, 1997; Wainer et al., 1999), one of the first papers to call attention to the dire need for research around score reporting was published by Goodman and Hambleton in 2004. This seminal paper reviewed current practices on score reporting and highlighted some of the main concerns around the ways in which score reports were designed and developed at the time. Primary among the issues highlighted in the Goodman and Hambleton paper was the inaccessibility of the communicated information. They highlighted the profusion of the use of technical language and inaccessible data presentation formats that are not comprehensible to the intended user. Following this paper there has been an increase in awareness of the critical importance of score reporting when it comes to stakeholder interpretation and use and its role in establishing validity arguments.

Since then, and particularly, in the last decade, score reporting has become a critical requirement within the request for K-12 state contract proposals in the United States, with the necessary push for some focus groups with the intended stakeholders to ensure appropriate interpretations and use of reported test scores. Moreover, there is a strong emphasis on score reporting across several chapters of the latest *Standards* (American Educational Research Association [AERA] et al., 2014), and particular emphasis on score reporting in Chapter 6 (Test scoring, reporting, and interpretation) where best practices around score reporting are set in standards 6.10, 6.11, 6.12, 6.13 and 6.16. Finally, research on issues surrounding score reporting has also substantially increased in the past decade with the necessary focus on audience specificity (Zapata-Rivera and Katz, 2014) in the design and development and on stakeholder interpretation and use (Kane, 2013) in the evaluation of score reports. Recently, NCME sponsored an edited volume on score reporting research and applications (Zapata-Rivera, 2019a), which includes a comprehensive set of edited chapters on the latest developments in score reporting research and applications. In this section, I will provide a broad overview of score reporting research that has been conducted in the last decade or more with particular focus on audience specificity and stakeholder interpretation and use of the results.

Audience specificity

Educational tests are developed and administered in various contexts with various purposes, each using a unique score scale, and typically have more than one intended audience or score user. Researchers (e.g., Marshall and Drummond, 2006; Underwood et al., 2007) have found that even teachers and administrators who are more in-grained within the larger context of education and assessments find a lot of the information reported in score reports to be inaccessible or impractical to their needs. Therefore, the results reported from each of these types of assessments should consider the needs and attitudes of the diversity of stakeholders (e.g., teachers, administrators, parents) who are likely to receive reports from and take actions based on the results.

In their influential paper on applying audience analysis to the design of score reports, Zapata-Rivera and Katz (2014) recommend that the needs, pre-existing knowledge, and attitudes (NKAs) of each stakeholder group be taken into consideration in developing audience-specific score reports. They point out that each stakeholder group such as parents, teachers, and administrators are likely to have different needs for information from the score report describing student performance on an assessment. In addition, they are each likely to have different levels of pre-existing knowledge about the assessment and its context, and have different attitudes, feelings, or biases that might color their interpretations of the information shown in the reports (Zapata-Rivera and Katz, 2014).

The majority of score reporting research, particularly in the last decade, has focused on identifying the NKAs of specific stakeholder groups such as parents (e.g., Kannan et al., 2018a, 2021b), teachers (e.g., Kannan et al., 2017, 2021a; Marshall and Drummond, 2006; Underwood et al., 2007; Zapata-Rivera et al., 2010, 2016), students (e.g., Corrin, 2019; Vezzu et al., 2012), and administrators (e.g., Hambleton and Slater, 1997; Kannan et al., 2017; Underwood et al., 2010).

Results from these studies highlight the diverse NKAs for each stakeholder group. For example, parents mainly want to know how their child has performed in an assessment, what these scores mean, and how they can help their child improve (Kannan et al., 2018a), but they may not be intimately aware of the assessment context and their attitudes toward assessments may sometimes be impacted by the media (Bennett, 2016). In contrast, teachers are particularly interested in information that can directly guide their instruction whether it is in the formative context (Brown et al., 2019) or for “receiving teachers” (p. 72) in the summative context (Kannan et al., 2017). And, administrators are most interested in average performance of the school or district population, resource allocation based on school/district performance, and program evaluation based on comparisons with other similar schools and districts (Kannan et al., 2017). However, teachers and administrators are often busy and have limited time to analyze volumes of data (Underwood et al., 2010). For example, teachers have often reported that they feel inundated with large volumes of raw student data which they find overwhelming to sift through, and due to this, researchers (Zapata-Rivera et al., 2010) have found that teachers may sometimes draw unwarranted conclusions from the scores.

Therefore, for the intended stakeholders to interpret the information accurately and use it appropriately, test developers should conduct an in-depth audience analysis before beginning any score report design process. Moreover, as Zapata-Rivera and Katz (2014) point out, the audience analysis should not just be considered a “mental exercise” (p. 13) at the beginning of the process. Rather, the intended stakeholder should be at the center of all decisions made at every step of the score report design and evaluation process.

Focus on stakeholder interpretation and use

As critical as it is to take the intended stakeholder's needs into consideration, it is equally, if not more important to evaluate the extent to which these intended stakeholders understand the information presented in the score reports and use these results appropriately. If the intended score user is either unable to understand the presented information or unable to glean how to use these results appropriately, the validity of the entire assessment may be called into question. Therefore, a lot of the focus within score reporting research (e.g., Kannan et al., 2017, 2018a; Zapata-Rivera et al., 2010, 2019; Zwick et al., 2014) has fittingly centered around stakeholder interpretation and use of the information presented in score reports. However, there is also a clear audience specificity in this line of research since stakeholder comprehension is understandably unique for each stakeholder group.

Prior to the recent momentum in score reporting research, score reporting was conducted as an ad hoc activity without much deliberation on the way in which information was presented in the score reports. This led to the inclusion of a lot of technical jargon and unclear data presentation formats that left score users confused and befuddled. In addition, cognitive aspects (Hegarty, 2019) such as perception, attention, working memory, and prior knowledge, which varies largely across individuals but also particularly between various stakeholder groups, also tends to play a critical role in the extent to which stakeholders can comprehend the information presented in score reports. Therefore, evaluating the appropriateness of the information for each stakeholder group is essential.

Parents were generally the most disadvantaged since they do not typically have the same type of background or orientation to the testing context as other stakeholders. Particularly with the unprecedented increase in large scale accountability testing since 2001, numerous score reports with metrics such as student growth percentiles (SGPs; Betebenner, 2009) and a variety of subscore indicators were being sent home to parents. A few researchers (e.g., Barber et al., 1992; Kannan et al., 2018a; Sireci et al., 2013; Zapata-Rivera et al., 2014) have focused on parents' interpretation and use of information presented in score reports. Research (Kannan et al., 2018a) has found that parents, who are a diverse and heterogeneous group, particularly, in terms of their education levels and English language proficiency, in general struggle to understand technical terms such as standard error of measurement (SEM) presented in score reports, and this is particularly the case for parents from underserved groups (Kannan, 2020).

However, rather than dismiss the need for the inclusion of such information in parent score reports, research indicates that parents desire the inclusion of technical information such as measurement error as long as it is clearly presented and explained (Kannan et al., 2021b). Moreover, the majority of the parents in previous research (Kannan et al., 2021b) have indicated that they are keen to understand the technical details of their child's performance especially when high-stakes decisions (e.g., retention or eligibility for participation in special programs) are to be made from their child's results. Overall, these results point to the importance of including clear supplementary information, possibly in multiple languages (Kannan, 2020), that helps aid parent comprehension of their child's results, and the need for clear guidance for both the interpretation and appropriate use of scores in parent score reports.

Even though teachers and administrators are likely to be more in-grained within the larger context of educational assessments, researchers (e.g., Marshall and Drummond, 2006; Underwood et al., 2007, 2010) have found that they also find a lot of the information reported in score reports to be inaccessible and/or tend to use the information for unwarranted purposes (Zapata-Rivera et al., 2010). Teachers have often been found to struggle to parse out some of the technical information presented in score reports (Impara et al., 1991; Underwood et al., 2007; Zapata-Rivera et al., 2012). In particular, teachers have been shown to have several misconceptions of complex technical concepts such as measurement error (Zwick et al., 2014), and the inclusion of brief tutorials (Zapata-Rivera et al., 2016) have been shown to be beneficial to aid teacher comprehension of such information.

Similarly, administrators and policy makers who are strapped for time have also been shown to be overwhelmed with large volumes of data (Kannan et al., 2017; Underwood et al., 2010), have trouble understanding the way in which data are presented (Hambleton and Slater, 1997) and draw unwarranted conclusions from the information presented in score reports. As a solution, Wainer et al. (1999) first proposed the evaluation of alternative visual displays with stakeholders—they found that simplified visual displays led to more accurate and faster responses by the policymakers. But, more importantly, Underwood et al. (2010) proposed an evidence-based framework for designing administrator and policy maker reports that links student data to focal questions that are directly linked to the types of decisions made by these stakeholders. Such reports designed to answer focal questions have been shown to result in better comprehension and foster appropriate use among administrators and policymakers (VanWinkle et al., 2011).

Iterative multistep framework for designing and evaluating score reports

Two related, but separately proposed, models for designing and evaluating score reports for large-scale educational assessments were offered by Zapata-Rivera et al. in 2012 and Hambleton and Zenisky in 2013. These models were largely informed by best practices in various aspects of test development (Hambleton and Zenisky, 2013) and by best practices in human-computer interaction (Zapata-Rivera et al., 2012), and offer a series of iterative steps to guide the score report development process. These models have been subsequently adapted and implemented in a number of research studies (e.g., Kannan et al., 2018b, 2019, 2021a) as an iterative multistep framework (see Fig. 1 below) that specifically focuses on stakeholder needs in informing the design and stakeholder interpretation and use in iteratively evaluating the score reports. In this section of the chapter, I will discuss the five major steps within the iterative multistep framework as presented in Fig. 1 with a major emphasis on the tools and evaluation methods that help with the implementation of this framework in practice.

Fig. 1 Iterative multistep framework for the design and development of score reports and reporting systems. Based on models proposed by Zapata-Rivera et al. (2012) and Hambleton and Zenisky (2013).

The iterative multistep framework starts with an analysis of the underlying claims of the assessment to ensure that the information communicated within the score reports are aligned to the test's purpose and an identification of the primary score users to ensure audience specificity in the design and development of the score reports. Next, preliminary mockups are designed based on an in-depth review of the literature and anticipating stakeholder needs. These preliminary mockups are used to elicit stakeholder needs by having them react to what's useful, confusing, and missing in the mockups. Once stakeholder needs are identified, the multistep framework continues through ongoing and iterative score report development and evaluation cycles. Finally, once score reports are operationally deployed, it is ideal to have continuous monitoring of the accessibility and usability of the reports within the changing context of the assessment and stakeholder needs to cycle back to the iterative process as needed. Each of the five major steps in this framework (see Fig. 1) are discussed in detail below.

Gather assessment information needs

A test's validity is dependent upon the extent to which the inferences made from the assessment results are appropriate and warranted based on the purpose of the test (Hubley and Zumbo, 2011; Tannenbaum, 2019). It is critical therefore to ensure that the score report, as the primary vehicle through which such inferences are made, is designed to reflect the test's underlying purpose and directly presents scores and results that are warranted based on the claims of the assessment. As such, the score report design and development process should always start with an evaluation of the assessment claims by conducting a client interview with the testing program (Slater et al., 2019) and evaluating the test's underlying claims and purpose.

Slater et al. (2019) provide a comprehensive list of questions that could help guide this conversation with the client, and include questions that are intended to identify the target audience or score user(s), the basic types of knowledge and skills measured by the test, the types of decisions that would be made based on this information, and if there are any complex metrics such as sub-scores or growth scores that need to be reported. These questions are intended to provide the necessary starting point to design some preliminary mockups.

Zapata-Rivera et al. (2012) introduced the concept of creating prospective score reports (or PSRs) while gathering assessment information needs. The PSR is a document that is used to gather client requirements and can include various pieces of information such as representations for scores and subscores from other reports developed in the past, definitions of skills, possible performance levels, etc. The PSR is then shared with content and measurement experts who can identify possible discrepancies and provide appropriate suggestions for including information relevant and appropriate to the assessment. The PSR can then serve as a starting point for designing the preliminary mockups that are used in the needs assessments with potential stakeholders. Moreover, designing PSRs early in the test design process also serves to guide test development process—in particular, this helps test designers to develop the test in a manner that helps capture the necessary data to support desired claims in an evidence-centered design approach (ECD; Mislevy et al., 2003; Underwood et al., 2010).

Design preliminary mockups

The design of preliminary mockups may start with some "napkin sketches" (p. 96) that are drafted during the initial client interview (Slater et al., 2019); this can also take the form of the PSR mentioned above. In developing these mockups, it is also useful to review

other existing score reports for similar testing contexts and stakeholders, which can provide both good and bad examples in terms of layout and graphical design. For ongoing maintenance and updates to existing score reports, the current score report can serve as the preliminary mockup. However, if substantial changes have occurred to the test's context and claims, then the current score report can be used to inform designers of any program-specific constraints that must be modified. Moreover, these preliminary mockups may also be informed by any audience-centric research studies in the past that may shed some light on the NKAs for the stakeholder group of interest. This review of the literature to identify audience-specific needs should not automatically be considered a replacement for conducting a needs assessment—these prior studies may provide guidance, but it is critical that the iterative score report design and development process also include stakeholder engagement to elicit specific needs for the context and purpose of the current assessment. In addition, for any static or interactive reports that will be housed in an online portal it is important to consider the latest Web Content Accessibility Guidelines (WCAG; currently WCAG 2.1). Finally, and most importantly, these preliminary mockups and subsequent score report prototypes should be informed by data visualization principles (Hegarty, 2019; Slater et al., 2019; Tufte, 2001).

Data visualization principles

Data visualization refers to the use of graphical representations to visually communicate data be it for communicating the pre-election poll results (see <https://projects.fivethirtyeight.com/2020-election-forecast/>), or the rate of disease spread such as with COVID 19 (see <https://covid19.healthdata.org/united-states-of-america?view=total-deaths&tab=compare>), or for communicating results from scientific experiments and large-scale educational assessments (Hambleton and Zenisky, 2013). These data can range from qualitative data (e.g., obtained from brainstorming activities or focus groups) to quantitative data (e.g., obtained from large-scale surveys and represented as a stacked bar chart as shown in Fig. 2).

When used as a tool for communicating information, data visualizations should be able to communicate the key message in a nutshell and be presented in a manner that aids the user's understanding of the data. For example, in Fig. 2, the main pattern to be observed is the high proportion of aging population in these first-world countries suggesting a possible decrease in birthrate. All other information, such as the actual proportions represented by each bar of the stacked bar chart is irrelevant to the main message, and would result in visual crowding, and potentially confuse the recipient of the data.

A lot of the work by Howard Wainer in the late 1990s (e.g., Wainer, 1997; Wainer et al., 1999) was focused on alternative visual representations of quantitative data that are intended to simplify the visual load, and aid in the comprehension of the illustrated relationships for the intended stakeholder. These explorations of alternative visual displays of quantitative information were responsible for sparking the increased interest in data visualization issues within score reporting. In addition, the influential work by Edward Tufte (2001) on the "Visual Display of Quantitative Information" serves as a foundational source of reference to score report designers and researchers alike in informing the design of quantitative data visualizations for score reporting.

Data visualizations should be informed by principles derived from graphic design and user-interface design (Evergreen and Metzner, 2013; Slater et al., 2019) and principles derived from cognitive science (Hegarty, 2019) that help delineate how people understand and reason about data. Slater et al. (2019) provide a list of principles that are specifically intended to guide the score report design process that include highlighting the key information that can be communicated at first glance and creating a visual hierarchy that guides the user as they review the report. Hegarty (2019) identifies a set of principles, informed by cognitive science and human information processing, that could be considered as heuristics for the design of data visualizations. She emphasizes the importance of presenting "no more or no less information" (p. 27) than is needed for the effective communication of the relevant

Fig. 2 An example of a quantitative data visualization (i.e., a stacked bar chart) which shows the proportion of population by age bands across select OECD countries in 2012. Data extracted from <https://stats.oecd.org/>.

message. In addition, [Hegarty \(2019\)](#) emphasizes the importance of ensuring that these representations are accurately interpreted. This highlights the importance of evaluating the interpretation and use of these visual displays which is highlighted in Step 4 of the iterative multistep framework.

Development of score report mockups and prototypes

In the context of reporting from large-scale assessment data, we are often interested in data visualizations that help to communicate results from student performance on standardized assessments to a variety of stakeholders. The users of a score report are typically neither experts of statistics nor experts in graphic design conventions and thus are not able to digest complex visual representations of technical and statistical information. In many cases, the users that receive the score reports do not have knowledge of the assessment context or content domain being assessed. Therefore, it is important to keep the pre-existing knowledge and background of the intended audience in mind as the score report mockups and prototypes are developed. A couple of hypothetical examples of such audience-centric score report mockups are presented in [Figs. 3 and 4](#).

A snapshot of a hypothetical student's score on a K-12 end-of-year summative assessment as would be typically presented in an individual student score report (or ISR) is shown in [Fig. 3](#). The intended stakeholder or recipient of the ISR is typically the student's parent or, in higher grade levels, the test-taker or student themselves. In this context and for these stakeholders, the most important pieces of information that should be highlighted in the score report are the student's score on the test, their performance level, any available normative comparisons (such as comparisons to average performance or percentile ranks), and any associated interpretive information that helps these users understand and appropriately use the test results (see [Kannan et al., 2018a](#)). As such, in this hypothetical example, the student's overall test score on the end of year mathematics test—as the most important piece of information—is highlighted prominently in this report. It is also easy to glean at a glance that there are three performance levels into which students can be classified and that this particular student has scored in the highest performance level (i.e., exceeds expectations). Additional information that is also likely to interest parents such as the student's percentile rank (or comparative performance) is highlighted. Finally, required interpretive information about the score reliability (i.e., the bar around the student's score) is also provided to ensure appropriate interpretation and use of the score results.

Fig. 3 Hypothetical example of the visual representation of an individual student's performance results on a K-12 end-of-year standardized assessment.

Fig. 4 Hypothetical example of the visual representation of a district report on a standardized assessment that shows the percentages of students in each performance level across the three elementary schools in the district.

In contrast, one slice of a hypothetical district-level performance report on a K-12 end-of-year summative assessment is shown in Fig. 4. The intended stakeholder or user of this information is likely a district administrator or data analyst in the district superintendent's office. District administrators are likely to have various questions as they explore district-level performance on a summative assessment (see Kannan et al., 2017; Underwood et al., 2010). The data visualization presented in Fig. 4 is but one of many slices of the district-level data. One critical need for a district administrator is to identify patterns in the data that inform their resource allocation decisions (see Kannan et al., 2017). The data presented in Fig. 4 are intended to help a district administrator identify patterns of performance across three elementary schools in a hypothetical district. The administrator may review these data to make appropriate resource allocation decisions and perhaps move some experienced teachers to Rob Town Elementary and focus on some targeted professional development for teachers from this school where the students may be struggling to "meet expectations."

In summary, it might seem counter-intuitive to design mockups before conducting an audience-focused needs assessment. However, in order to be able to orient the study participants to the purpose of the assessment, and provide some possible solutions to the needs that are elicited to see what works and what does not work, it is recommended that some preliminary mockups are designed ahead of the stakeholder needs assessments. This methodology is borrowed from user experience research (Kinzie et al., 2002; Kujala, 2008; Silver, 2005) wherein preliminary solutions are presented after eliciting needs in a user-focused needs assessment, and users are asked to evaluate the preliminary solution to determine what works and what does not. In the audience-centric focus that has been followed in score report design and development (e.g., Kannan et al., 2018b, 2019, 2021a), a similar methodology is followed where preliminary mockups are presented after stakeholder-specific needs are elicited, and participants are asked to evaluate these preliminary mockups for what they like, dislike, and find confusing.

Conduct user-centered needs assessments

A "needs assessment" is defined as a systematic process for addressing the gaps between "what is" and "what should be" (p. 3)—in other words, identifying the discrepancies between what is currently available and what is desired (Altschuld and Kumar, 2010). Since score reports play such a critical role within the validity argument for a test, reports should be designed to address the gaps in terms of stakeholders needs, so that they are able to interpret and use the assessment results accurately and appropriately. Moreover, it is clear from score reporting research, that each stakeholder group has unique needs, necessitating user-specific needs assessments for each stakeholder group.

Using focus groups and surveys to conduct user-centered needs assessments

Focus groups can serve as an economical and efficient way of getting in-depth feedback from multiple participants in a setting where they do not feel threatened (Onwuegbuzie et al., 2009). In the context of score report design, focus groups serve as an efficient method to obtain a deep understanding of stakeholder needs by delving into questions about their current experiences and pain points, before eliciting their context-specific needs, and subsequently having them react to some preliminary mockups. For each stakeholder group, it is advisable to schedule and conduct at least 3–5 separate focus group meetings with about 5–8 participants each in order to achieve data saturation—that is, until no additional new categories are identified in subsequent focus groups.

(Onwuegbuzie et al., 2009). In some previous studies (e.g., Kannan et al., 2021a), up to six separate focus groups have been conducted with the intended stakeholder group (i.e., teachers) in order to achieve data saturation.

A sample schedule of activities (as implemented in Kannan et al., 2018b, 2019, 2021a) is presented in Fig. 5. Five broad types of activities, starting from a pre-meeting survey and ending with a post-meeting survey, are recommended in conducting a user-centered needs assessment. In the current environment (i.e., during and post COVID-19), it is also important to note that all the activities detailed within this section can be conducted remotely via a combination of pre-meeting and post-meeting surveys conducted online, and a virtual focus group meeting conducted via a platform such as Zoom (<https://zoom.us/>). Virtual meetings can help with increasing the diversity of study participants by expanding access to participants in different locations; however, it may also serve to exclude those without access to reliable internet—though, this concern has become less ubiquitous with increasing access to high-speed internet globally. The pre- and post-meeting surveys help supplement the focus groups in identifying gaps ahead of the meeting and prioritizing needs at the end of the meeting. In this section, I will provide a broad overview of the activities listed in Fig. 5.

Pre-meeting survey

As a first step, previous studies (Kannan et al., 2018b, 2019, 2021a) have recommended the use of online pre-meeting surveys to elicit participant feedback. The purpose of this pre-meeting survey is to get a general idea of the types of reports that stakeholders currently receive and what they may like or dislike about these reports in order to identify some pain points and gaps. It is a good idea to send participants a link to the survey about 2–3 weeks prior to the scheduled focus group and request responses at least 3–5 days before the meeting to generate some conversation starters for the first whole-group discussion.

Whole-group discussion

As indicated before, participants may be convened for either an in-person or virtual focus group. Once the participants have been provided with a basic introduction to the assessment, its claims, purpose, and context, this whole group discussion can be used to set the stage for the overall needs assessment. A structured protocol may be used for this whole group discussion to identify the types of reports that stakeholders currently receive, what they like and dislike about the current reports, and the types of feedback they would desire and consider most useful in this context. The responses provided to the pre-meeting survey should be analyzed ahead of time for themes and used as conversation starters during this discussion.

In addition, participants may be called upon to comment about specific types of reports or report slices that have been used in the past and identified based on either a review of the literature or a review of other existing reports. For example, in a focus group with teachers, they may be specifically asked to react to the need and importance of various types of feedback typically found in class-level reports, such as rosters with tabular information, or distributions of student scores based on strengths and weaknesses.

Overall, the goal of this discussion should be to elicit a list of needs based on some of the gaps identified in terms of what they currently have and what they would ideally desire in score reports. The focus of the structured prompts should be to identify gaps based on intended uses and decisions for the stakeholder group, and thereby identifying the types of data or supporting information

Sample Schedule of Activities for a Needs Assessment Focus Group

I. Pre-meeting survey

Used to get a **general idea of current experiences** and generate some conversation starters during the focus group.

II. Whole-group discussion

Used to **build on the responses provided in the pre-meeting survey**, and facilitate a conversation around what types of reports they currently receive and what types of feedback they would value.

III. Individual work

Used as a **proxy for a problem/solution interview** and elicit individual needs – where needs are elicited, mockups are presented as one potential solution, and then mockups are evaluated

IV. Small group discussion

Used to explicitly **identify needs not addressed** in the mockups.

V. Post-Meeting Survey

Used to **prioritize and rank-order needs**

Fig. 5 Sample schedule of activities in a user-centered needs assessment focus group study [as implemented in Kannan et al., 2018b, 2019, 2021a].

that can be provided in the score reports to specifically support those uses and decisions. During the whole group discussion, a structured call-out format is recommended, where each participant is called upon to respond in a systematic pre-determined order so that no one person goes first or goes last always, and everyone gets a chance to weigh-in on the discussion.

Individual work

The overall goal with the individual work is to be able to evaluate the preliminary mockups and to identify specific rank-ordered needs for each individual participant and see if some needs are seemingly more important than others. This part of the focus-group is mainly meant to serve as a “problem-solution interview” (a terminology borrowed from UX research) where individual participant needs are identified and the extent to which the preliminary mockups serve as a solution to the identified problems (i.e., needs) is evaluated. To identify individual rank-ordered needs, in previous studies (e.g., Kannan et al., 2018b, 2019, 2021a), participants have been asked to reflect upon the preceding whole-group discussion and list their individual top 5 needs for information in the score report. Once the rank-ordered needs are elicited, the score report mockups are then presented to the entire group, and participants are asked to evaluate each report page or screen. In order to evaluate the mockups, participants are typically provided with printed screenshots of the mockups with multiple colored pens, and asked to mark up what they like, what they dislike, and what they find confusing.

In one previous study, Kannan et al. (2021a) used virtual focus groups so as to include a representative sample of teachers from across the country. In this study, an online heatmapping tool, as presented in Fig. 6, was used. Participants used the heatmapping tool to click on various areas of each report screen to indicate whether this was something they particularly liked, or disliked, or found confusing. Then, participants elaborated by providing detailed comments associated with each click. These clicks and associated comments were later analyzed and summarized to understand the extent to which the preliminary mockups served participant needs and what if anything could be changed or further clarified. In addition to having participants evaluate what they like and dislike about the current mockups, they should identify if any of their most important needs are not being addressed in the current mockups. The subsequent small-group discussions are used for this purpose.

Small-group discussion

The main purpose of the small group discussion is to consolidate participants’ individual evaluations of the mockups and identify what is missing from the mockups vis-à-vis needs that were identified both at the individual and group levels. In previous needs assessment studies (e.g., Kannan et al., 2018b, 2019, 2021a), participants have been asked to reflect upon the rank-ordered needs and consolidate these needs within their groups. Then participants use these group-level needs to evaluate the mockups and identify needs from their group-level list that have not been addressed in the preliminary mockups. Participants can be provided with flip-charts or notepads to discuss and summarize this information that can then be collected at the end of the meeting. In an online/virtual setting, breakout rooms with individual facilitators assigned to each breakout room may be used to achieve the same results.

Fig. 6 Heatmap results for one of the 6 screenshots for mathematics teachers identified in Kannan et al. (2021a). Each thumbnail in this figure shows the density of clicks for likes, dislikes, and confusions indicated by participants as they evaluated one mockup screen; each of these clicks was also linked with associated comments that helped identify the report elements that were particularly liked, disliked, and confusing to the participants and informed subsequent prototype revisions.

The room facilitators can use online tools such as MS-OneNote to help capture the discussions and to identify the critical stakeholder needs that have not been addressed in the preliminary mockups.

Post-meeting survey

A variety of needs may be identified during the needs assessment focus groups, but for various practical considerations, it may not be feasible for the testing program to prioritize all of these needs in their score report prototype development. Moreover, regardless of the total number of focus groups conducted in the attempts to achieve data saturation, it should be recognized that data from focus groups are based on qualitative evaluations of small samples and may need to be validated. Therefore, the needs identified in the focus groups should be prioritized based on their importance by conducting a post-meeting survey with a larger group of stakeholders. In one previous study, [Kannan et al. \(2019\)](#) listed all the needs generated during the focus groups in an online survey using a Likert-type scale where participants rated the importance of each need for themselves and for other teachers in a similar context (e.g., ESL teachers, special education or remedial teachers, regular classroom teachers). It is important to try to include a reasonably large and diverse sample for the post-meeting survey to be able to generalize the results from the needs assessment to the larger stakeholder group. The results from the survey may then be used to rank order and prioritize needs for subsequent prototype development. For example, all needs with average importance scores of 4 or above (on a 5-point Likert) may be identified as top needs that are then summarized and provided to the designers for implementation into the next iteration of prototypes.

Develop prototypes and iterate with systematic feedback

Once the most critical needs are identified for each intended stakeholder group, the iterative prototype design process can then begin. The evaluation of the preliminary mockups and additional needs, if any, that are identified during the needs assessment are shared with the UI/UX graphic designers. The data visualization principles and WCAG compliance noted in Step 2 are again critical to consider in the design of functional prototypes. However, the most important aspect of the iterative prototype development cycle is the adoption of an agile methodology and repeated engagement with the stakeholders to evaluate that the scores, tables, or visual representations, and any additional supplementary information presented in the report prototypes are accurately interpreted and appropriately used. Therefore, during each iterative design and revision cycle, cognitive interviews and usability studies should be scheduled with the intended stakeholders to evaluate their comprehension of the presented information, their preference for alternate visual representations which are substantiated by the interpretability of each alternate representation, and the usability of any interactive interface.

Cognitive interviews and surveys to evaluate stakeholder comprehension and usability

Since a test's validity is dependent on the extent to which stakeholders can understand and interpret the information presented in score reports, it is critical to iteratively evaluate how stakeholders comprehend this information and make appropriate revisions where additional clarity may be needed. Study participants should be ensured that the comprehension questions are not intended as a test of the participant's knowledge, but rather to evaluate how well the reports have been designed to convey necessary information. Moreover, for online and interactive reporting systems, participants' ability to engage with the interface, access all relevant information, and use the interactive features designed for data manipulation, also have an influence on stakeholder comprehension of the information and should also be systematically evaluated. Evaluation of participant comprehension and usability may be done either through embedding report snapshots with associated questions in an online survey or through engaging with participants in cognitive interviews, where participants are asked to verbally respond to focused questions either during engagement in an activity or after they have completed the activity ([Keehner et al., 2016](#)).

Some previous studies (e.g., [Kannan et al., 2018a](#); [Kannan, 2020](#)) have used a hybrid cognitive interview style which combines retrospective verbal probing where participants respond to directed questions with concurrent think-aloud methods where participants verbalize their thoughts as they are interacting with the report or reporting system. These cognitive interviews are intended to identify the elements in the score report that are most salient to the stakeholders and if they are able to access and use all the information as intended in addition to evaluating if the information presented in these reports is interpreted accurately. In other studies (e.g., [Kannan et al., 2017, 2021b](#)), specific comprehension questions pertinent to the range of information provided in the reports were embedded in online surveys. These survey studies have included several questions that are quick to answer (such as multiple choice, true/false), and focused these questions on aspects of the representations that may likely be confusing given the specific knowledge and constraints of the intended stakeholder group. Participant responses to these comprehension questions then enable test developers to evaluate the extent to which the data visualizations and other information presented in the reports are being understood correctly and identify areas where additional clarity may be needed.

Surveys and interviews to evaluate stakeholder preference

In addition, it may be important to evaluate if different alternative visual representations lead to more accurate interpretation of the key information presented in the score reports. It is possible that certain representations are not as easily understood by certain stakeholder groups. For example, for parents, who may not have the necessary statistical background, simple bar and line charts may be more readily understood than more complicated representations such as box and whisker plots and bubble charts. In addition, information on stakeholder preference for one visual representation over another can be collected; however, feedback on

preference should always be substantiated by improved comprehension. Just preference of one representation does not justify its use if it does not also lead to better comprehension of the presented information.

In one previous study (Kannan et al., 2017), researchers anticipated that a preliminary design that represented sub-area performance in terms of a spider-web diagram (or radar chart) would possibly be less familiar to some stakeholder groups (i.e., teachers, principals, and district administrators). Therefore, two alternative representations for sub-area performance were designed and included for evaluation, specifically, stacked bar charts with scale scores and multiple column bar charts with percentages. Results from this study indicated that principals and district administrators had a strong preference for the multiple column bar charts with percentages, whereas teachers had a slight preference for the stacked bar charts with scale scores. Both these alternative representations resulted in significantly higher levels of comprehension than the original spider-web diagrams, which were unanimously not preferred by any of the stakeholder groups (Kannan et al., 2017).

Operational deployment

Score report prototypes should be iteratively and systematically evaluated with both internal clients and the larger stakeholder group until the interviews and surveys indicate that there are no undue misinterpretations of the reported results. There is no ground rule on the required number of iterations before score reports are finalized. This has to be guided by the data and may also be based on program directions and other operational constraints such as pre-determined test launch-date. Slater et al. (2019) provide a broad overview of the operational score report design process and identify several operational constraints that may be encountered during the iterative design cycles. Once score reports are operationally deployed, a program for on-going maintenance and continuous monitoring of the score report interpretation and use should be set in place. Large-scale surveys may be used to evaluate how stakeholders intend to use the data presented in these reports and the decisions they will make based on the reports.

Large-scale surveys to evaluate intended uses and decisions

A systematic evaluation of the uses and decisions to be made from the reported data is also important to ensure a test's validity. In other words, the extent to which stakeholders understand how the results may be used (i.e., appropriate next steps), and the types of decisions that they intend to make from the reported results should be evaluated for each stakeholder group. The uses and decisions made from the score reports should not lead to negative unintended consequences that undermine the validity of the test. One previous study (Kannan et al., 2017) specifically evaluated stakeholder use and decisions made from the data presented in reports by embedding directed questions about intended use and decisions in an online survey with large samples of teachers, principals, and district administrators. Results from this survey helped the testing program ensure that appropriate and warranted decisions were being made based on the reported results. Similarly, all testing programs should continue to evaluate if the operational reports are functioning as intended and that the results presented in the reports are being used in the manner intended. If there are indications of inappropriate use, actions should be taken to revise and update the reports to clearly present information about intended uses so that the program can mitigate any unintended consequences from inappropriate use of test results.

In addition, state departments and testing programs should continuously monitor that reports continue to remain useful over time as changes are made to the test or the testing context. There may be changes initiated to the ways in which the data from the test are analyzed and scored, which results in the need to communicate results from new models. There may be new federal or state mandates that require the reporting of new metrics, for example to report student growth across the years. Each of these types of changes may result in the need to report either new metrics or include additional visual representations or both. Such additions/revisions to the existing score report should be evaluated for interpretability and appropriateness for each stakeholder group. Moreover, tests are often revised over time, and if these revisions are substantial wherein they impact the underlying claims based on the test, then the entire iterative design and development process starting with a needs assessment should again be undertaken. For on-going program maintenance, the iterative process can directly start in Step 3, and the current score reports can serve as preliminary mockups to identify gaps and conduct a needs assessment with the intended stakeholder group(s). Regardless, and for a multitude of reasons only some of which are listed here, it is important to establish a program of on-going maintenance and monitor if the score reports continue to communicate test results to the intended stakeholders in a manner that fosters appropriate interpretation and use.

Future of score reporting research

Score reports are the “bridge” (p. 9, Tannenbaum, 2019) that help link what is measured in a test to how stakeholders use that information. Therefore, the information communicated through the score reports should be iteratively evaluated to ensure that stakeholders are able to interpret and use the information in appropriate ways. In this chapter, we reviewed research that has been conducted on audience-centric score reports and how specific audiences interpret and use score reports. We also reviewed an iterative multistep framework with suggested research-based methods for the design and evaluation of score reports. This framework provides a clear, research-based, set of steps with a guidance on specific methods to follow in developing and evaluating score reports for new and existing testing programs. Though a number of applied research studies have been conducted in this context, additional research should be conducted that focuses on supporting stakeholder interpretation and use, particularly around sub-

score reporting and growth metrics (Zenisky and Hambleton, 2012). But overall, interest around interactive reporting systems has been burgeoning and this focus for future research would be very apropos given the current shift toward a predominantly virtual world.

Interactive reporting systems

Research in score reporting has largely focused on static score reports, whether these are printed score reports or accessed through an online portal. National and International assessment programs such as the National Assessment of Educational Progress (NAEP), Trends in International Mathematics and Science Study (TIMSS) and the Programme for International Student Assessment (PISA) have pioneered in the area of dashboard reporting and interactive reporting systems. In recent years, there has been an increasing momentum in the development of interactive reporting systems in the context of various large-scale K-12 assessment programs, especially for some stakeholders such as teachers and administrators, who have to review group-based data and make instructional or administrative decisions based on data available in score reports. Moreover, there has also been some interest in developing and housing interactive score reports with various other supporting and supplementary information even for stakeholders such as parents so that they may access all assessment related information in a single location such as a parent portal.

These interactive reporting systems have a “high degree of user choice” (p. 25) in the ways in which stakeholders access and obtain the information (Zenisky and Hambleton, 2012). These reporting systems are typically housed in websites where users arrive at a landing page, and then make a series of decisions about the type of data they want to explore and the order in which they want to explore these data. Therefore, these interactive reporting systems should offer a high degree of flexibility where each user can take their own unique path to explore the system. However, it is important to ensure that each slice of the reporting system is developed with a keen focus on audience-specificity and ensuring that these slices do not lead to unwarranted interpretations and uses for the stakeholders.

There are a variety of issues to consider in designing and developing such reporting systems. In essence, every slice or view of the reporting system may be considered a pre-canned report that is developed using the iterative framework. The important slices that are relevant to each stakeholder group can be identified through a needs assessment, and question-based reporting (VanWinkle et al., 2011) may help target users to specific slices that clearly answer a user-based need within the score report. In addition, higher-level decisions about what the user would want to see first and the ability for the user to navigate back and forth from each screen or reporting slice to any other location in the system should be carefully considered. Research in the area of software and web content development and user interface design can largely inform the research on developing reporting systems. These reporting systems, dashboards, and portals should be carefully designed and evaluated by applying and extending the iterative multistep framework to the design and evaluation of reporting systems. Some of the early work around the evaluation of NAEP dashboards (Zenisky et al., 2009) is a great start in this area, but additional work is needed.

In addition to the need for research on the design, development, and evaluation of interactive reporting systems, there are several other emerging areas of research within score reporting. These include: score reporting for formative purposes (Kannan et al., 2018b; Zapata-Rivera et al., 2018), score reporting of process data (e.g. Zapata-Rivera et al., 2018), research around data analytics and dashboards (e.g., Bodily et al., 2018; Corrin, 2019), and work on visualizing information from adaptive instructional systems (e.g., Zapata-Rivera, 2019b). Additional research in each of these areas is warranted, but continuing to understand the extent to which stakeholders are able to interpret and use the score reports in each unique assessment context continues to remain important. Overall, though score reporting research has come a long way from being one of the most under-researched areas in measurement about 10 years ago (Hambleton and Zenisky, 2013), much still remains to be understood.

Introduction

In the last fifty years, international migration of people living in a country other than their birth country has grown steadily. In 2019, the number of international migrants grew globally to 272 million, or 3.5% of the world's population, up from 84 million or 2.3% in the year 1970 ([International Organization for Migration, 2019](#)). A recent Pew Research Center analysis found that individuals in the United States who were born after the year 2000 are the most racially and culturally diverse yet ([Fry and Parker, 2018](#)). These changes in diversity greatly impact student populations and place unique demands on systems of education. Students categorized as English Language Learners (ELLs) – those who are learning content in English while also gaining proficiency in this language ([Valdés, 2004](#)) are the fastest-growing segment of the school-aged population ([Grantmakers for Education, 2013](#); [National Education Association, 2015](#)).

For decades, educators have been concerned that differences in English language proficiency skills may contribute to measurement error on assessments, with a wide range of potential consequences for ELLs' educational programming and opportunities to learn. Language proficiency has been shown to greatly affect student performance on academic assessments, even when language is not the focal construct of the assessment ([Abella et al., 2005](#)). ELLs tend to perform lower than native English speakers on standardized tests that are offered in English, especially on tests with higher language demands ([Abedi, 2002, 2009](#)). Lower test scores may be misinterpreted as evidence of academic deficits, resulting in placement into remedial courses ([Callahan and Shiffrer, 2016](#); [Kanno and Kangas, 2014](#)) and potentially incorrect special education diagnoses. In fact, educators and researchers have been alarmed at the disproportionate overrepresentation of ELLs into special education programs and underrepresentation in gifted and talented programs, relative to ELLs' representation in the overall student population ([Abedi, 2009](#); [Donovan and Cross, 2002](#); [Ford et al., 2008](#); [Sullivan, 2011](#)). It is thus vital that test developers and users attend to linguistic factors in assessment, which include translation and adaptation processes.

In situations where the focal construct is unrelated to language proficiency, a translation of the assessment may be an appropriate step in ensuring the validity of the assessment results. For example, in New York State, a number of statewide Regents exams are translated from English into the top five home languages of the state (i.e., Chinese, Haitian Creole, Korean, Russian, and Spanish). These exams are eligible for translation because the constructs being measured, such as Algebra or Global History, are considered unrelated to English language proficiency. In the international context, large scale assessments of student proficiency (e.g., the Programme for International Student Assessment) are often translated into various languages so that students' academic skills are assessed in their home language, and subsequently their performance on a construct can be compared across regions. Beyond the translation of an assessment from one language to another, assessments may also need to be adapted for cultural purposes so that test questions are appropriate for the students' context. This article describes these types of situations and processes, and in doing so, contributes to an understanding of the complexity of translation and adaptation of assessments for ELL students.

The importance of translation and adaptation

When test items include high linguistic demands, language factors may prevent students from demonstrating their domain-relevant knowledge, thus introducing sources of systematic error into students' test scores ([Abedi, 2014](#); [Messick, 1994](#)). When students from a wide variety of linguistic backgrounds are assessed using the same assessment instrument, the test questions may be adapted so that students can experience the questions in a comparable way. The true comparability of test questions is a central concern because test results are often used for making important decisions based on performance. For instance, using the examples described

above, New York State uses their Regents exams for the high stakes purpose of graduation. Students must successfully pass five Regents exams in order to graduate with a New York State Regents diploma. However, given the diversity of home languages of students from across New York, translated assessments are one effort toward promoting equitable graduation criteria. International assessments are another example, wherein students from across the globe are assessed so that the educational practices of various countries and regions can be compared. Policy decisions are frequently made based on outcomes from these international assessments (Carnoy, 2015). Clearly, it is imperative that linguistic and cultural factors are considered and addressed so that assessment results can be interpreted in an appropriate manner, both locally and internationally.

Translation and adaptation defined

It is important to distinguish between test translation and adaptation for the purposes of cross-cultural and linguistic assessment before moving on to the other sections of this article. Test translation refers to converting test items and associated text, such as directions or tutorials, from one language into a second target language. Adaptation refers to the broader practice of ensuring the appropriateness of various test forms, with the goal of achieving true comparability. In the context of culturally and linguistically diverse test takers, adaptation encompasses traditional translation activities; however, it may also include additional actions such as the modification of test layout to fit a new language or culture (e.g., formatting text so that reads from left to right) and determining whether two tests measure the same constructs equivalently after adjustments are made for a new language or culture.

Adaptation is sometimes needed when translation is not necessary, such as when two populations use the same language, but have different meanings associated with some words or phrases. There are many examples from languages that are used in more than one region. Consider, for instance, that Quebec French spoken in Canada varies from Metropolitan French which is spoken in France. In Metropolitan French, the word for bicycle is *vélo*, however the Quebec French equivalent is *bicyclette*. Another example is how lemon and lime are translated into Spanish, or whether the two types of fruit are distinguished at all. Lime can be referred to as *limon verde*, *limón*, or *lima*, depending on the locale of the speaker. However, *limón* or *lima* is also used to refer to lemons in some Spanish-speaking countries. For instance, requesting a *limón* in Chile will result in the large yellow citrus fruit, whereas asking for a *limón* in the Dominican Republic will produce the smaller green fruit. In each country, the alternative citrus fruit (that is, a lime in Chile or a lemon in the Dominican Republic) is rarely found, which can further complicate the issue of differentiating between the two. These examples of French and Spanish lexicons demonstrate that test adaptation may be a necessary step beyond full text translation because the meaning of words may differ across regions that share the same language.

Validity and construct irrelevance

Validity refers to the degree to which empirical evidence supports the appropriateness of test score interpretations (American Educational Research Association et al., 2014). Test validation involves searching for sources of both confirming and disconfirming evidence related to interpretive arguments, as well as identifying underlying assumptions that may or may not be credible in relation to the evidence collected (Haertel, 1999; Kane, 1992). Test developers collect various types of evidence to build a validity argument, including but not limited to evidence from expert judgments, test taker response processes, cognitive interviews, and statistical analyses. For instance, if the purpose of a test is to make a judgment about a student's mathematical skills, a test developer would collect validity evidence to support the conclusion that the test score is in fact a reflection of students' mathematical knowledge.

Construct irrelevant variance is "the degree to which test scores are affected by processes that are extraneous to the test's intended purpose" (American Educational Research Association et al., 2014, p. 12). Language ability is a potential source of construct irrelevant variance that may artificially deflate ELLs' scores on assessments. For example, a test would be affected by construct irrelevant variance if the test were designed to measure mathematics ability, despite inadvertently measuring language proficiency due to high linguistic demands in the wording of test items. The test validation process may reveal that test takers' language abilities may affect the test score interpretation. In this scenario, test developers may find that a translation or adaptation of a test is a useful way to reduce construct irrelevant variance. It should be noted that interpretations of a translated or adapted test also must undergo the same validation processes.

The process of translation

The actual process of translating or adapting a test may be time consuming and laborious. However, it is necessary in order to ensure the comparability of test forms. During the translation of a test, a common first step is to perform what is known as a forward translation. This procedure involves translating the test from its original language into a target language. Great care should be given to how the translators are chosen in that they should be fully bilingual in both languages, but also aware of variations in the languages that they are working with. Beyond extensive knowledge of language and context, the translators should also have knowledge about the construct that is being assessed.

A back translation may then be subsequently completed, wherein the test is translated from the target language back to the original language in which the test was developed. This step should be conducted by independent translators, that is, individuals

who did not conduct the initial forward translation. This stage would ultimately yield two versions of the same test in the original language. It can be very helpful for test developers to compare the two versions to determine if the original meaning of the test has been preserved after a back translation.

Finally, following the back translation, a harmonization step takes place. During harmonization, a bilingual panel reviews both the original and the translated test items. This panel aims to reach a consensus on the quality of the translation that took place, and whether meaning of words or concepts have remained constant during the translation process. The panel also explores how to remedy any possibly discrepancies that have emerged due to the translation process (Abubakar et al., 2013).

Poor translation and adaptation

When a test is translated from one source language into another, differences between the test forms may be unfair for a variety of reasons. These differences can include text length, complexity, or changes in actual meaning. For instance, Goodrich and Ercikan (2019) describe the example of French and English versions of the 2011 Progress in International Reading Literacy Study (PIRLS), which is an international assessment of reading for students in the fourth grade. The authors used expert reviews to examine the construct equivalence of French and English passages used in the assessment. In some passages, reviewers found differences such as longer and more confusing French text when compared to the English version, and also noted that for one passage, font size was smaller in the French version than the English version. It was noted that some words in the French version of the assessment were not commonly used by French language groups in Canada, or were more difficult than the English term that was translated. For instance, in one passage, the English term “looked like” was translated to “*apparence extérieure*” – a term that translates more closely to “external appearance” in English. This example highlights the care that must be taken to ensure the resulting translated items are truly measuring equivalent constructs.

At times, poor translations provide one group of students with more information about an item, or a hint at the correct answer, compared to what the other group of students will see. An example of this was presented in Ercikan and McCreith (2002) who also examined French and English versions of another international assessment, the Trends in International Mathematics and Science Study (TIMSS). In one translation of an item, the term “oxygen equipment” is translated to the more informative “*bouteilles d’oxygène pour respirer*”. The addition of “... *pour respirer*” inserts the additional term “for breathing” into the phrase. Another example is found in research conducted by Ercikan et al. (2010) in which an item from a Canadian nationwide assessment presented a diagram of clocks with two different times displayed. Students were then asked to measure the degrees of movement of the minute hand. The English version of the question asked students, “How many degrees does the *minute-hand* move from 3:25 pm to 3:45pm?” whereas the French version asked students “De combien de degrés *la grande aiguille* s’est-elle déplacée de 15 h 25 à 15 h 45?”. In this situation, the term “minute-hand” was translated to “*la grande aiguille*”, which back-translates into “long hand”. In order to correctly answer the question, students taking the English-version of the assessment would need to first know that the minute hand was the longer hand of the two hands of a clock, and then calculate the degrees of movement of that hand. The French students are required to take one less step to answer the question, given that the stem of the question indicates to the students the clock hand that they need to examine.

While comparability of two language versions of a test is a primary goal during test translation, one area of research has highlighted how traditional translation procedures may focus too narrowly on the equivalence of the translated versions. With the potential to be heavily influenced by confirmation bias, scholars argue that it is critical to focus on actively searching for translation issues throughout the entire test development process. The Theory of Test Translation Error (TTTE) was proposed to address these important issues (Solano-Flores et al., 2009). According to TTTE, translation errors are observed when the original and translated test versions differ in terms of design, language and content. Such errors are inevitable, given that each language encodes meaning differently. By actively anticipating such issues, the goal is to minimize translation errors to the greatest extent possible (Solano-Flores et al., 2009).

Inappropriate uses of translation and adaptation

As noted above, translations may be an appropriate step to take if the assessment content can be translated into a target language or context without altering the construct. However, there are scenarios where translations may not be appropriate. For example, the translation of an assessment measuring English language proficiency into any home language would not produce results that can be used in an appropriate manner, because the construct of measurement would be altered. English language proficiency assessments are often administered to students to determine the appropriate level of English language services to which a student is entitled. Therefore, translating any section of this type of assessment into a student’s home language would be inappropriate. Another example would be the translation of an English Language Arts (ELA) assessment into a students’ first language, given that language arts are unique to each language (e.g., poetry rhymes cannot be replicated exactly) and the structure of language differs across languages (Solano-Flores and Hakuta, 2017). Thus, translating an ELA assessment would distort the construct being measured.

When it has been determined that a language arts assessment should be made available to students in another language, some assessment programs have created a new assessment in the target language. For example, the Colorado Department of Education has

created a Spanish Language Arts (SLA) assessment as an accommodated form of its ELA assessment. This tool is aligned to its English counterpart, but it is not a translation of the ELA assessment. Rather, it is a high-quality assessment that was created to measure the language skills of those students who are designated as English Learners and are also native Spanish speakers. The benefit of this type of tool is that students' knowledge and skills can be measured in their home language, as the construct being measured is now independent of English language ability.

ITC guidelines

Given the frequent need for test translation and adaptation, and the common mishandlings of this process, the International Test Commission (ITC) has created guidelines for translating and adapting tests (ITC, 2017). The first edition of these guidelines was released in 2005 and the second edition, revised to reflect changes in both technology and practices, was released in 2017. The ITC identified six unique categories for translation and adaptation, into which 18 guidelines are categorized. These six categories include (1) Pre-condition, which refers to the conditions that take place prior to translation and adaptation; (2) Test development, or the point at which adaptation takes place; (3) Confirmation, which are the practices needed in order to verify construct equivalence, validity, and reliability after adaptation has taken place; (4) Administration; (5) Score scales and interpretation; and (6) Documentation.

In the pre-condition category, proprietary issues as well as general context are taken into consideration. The guidelines for the pre-condition category are:

- (1) Obtain the necessary permission from the holder of the intellectual property rights relating to the test before carrying out any adaptation.
- (2) Evaluate that the amount of overlap in the definition and content of the construct measured by the test and the item content in the populations of interest is sufficient for the intended use (or uses) of the scores.
- (3) Minimize the influence of any cultural and linguistic differences that are irrelevant to the intended uses of the test in the populations of interest.

The test development category takes into consideration the issues that may arise during the process of translating and adapting the test:

- (4) Ensure that the translation and adaptation processes consider linguistic, psychological, and cultural differences in the intended populations through the choice of experts with relevant expertise.
- (5) Use appropriate translation designs and procedures to maximize the suitability of the test adaptation in the intended populations.
- (6) Provide evidence that the test instructions and item content have similar meaning for all intended populations.
- (7) Provide evidence that the item formats, rating scales, scoring categories, test conventions, modes of administration, and other procedures are suitable for all intended populations.
- (8) Collect pilot data on the adapted test to enable item analysis, reliability assessment and small-scale validity studies so that any necessary revisions to the adapted test can be made.

Confirmation guidelines provide direction on best practices for ensuring that the translation and adaptation are suitable for the target population, after the process has taken place. These guidelines include:

- (9) Select sample with characteristics that are relevant for the intended use of the test and of sufficient size and relevance for the empirical analyses.
- (10) Provide relevant statistical evidence about the construct equivalence, method equivalence, and item equivalence for all intended populations.
- (11) Provide evidence supporting the norms, reliability and validity of the adapted version of the test in the intended populations
- (12) Use an appropriate equating design and data analysis procedures when linking score scales from different language versions of a test.

Administration guidelines are given to ensure that translation and adaptation are appropriate when the assessment is administered to examinees. These two guidelines are:

- (13) Prepare administration materials and instructions to minimize any culture- and language-related problems that are caused by administration procedures and response modes that can affect the validity of the inferences drawn from the scores.
- (14) Specify testing conditions that should be followed closely in all populations of interest.

The score scales and interpretation guidelines are provided to support inferences about examinees' scores:

- (15) Interpret any group score differences with reference to all relevant available information.
- (16) Only compare scores across populations when the level of invariance has been established on the scale on which scores are reported.

Finally, documentation guidelines are provided. The authors of the ITC guidelines note that documentation is often neglected in test adaptation. These guidelines are particularly important because they support the test user, and may also be used as a blueprint in future test adaptations. Guidelines pertaining to documentation include:

- (17) Provide technical documentation of any changes, including an account of the evidence obtained to support equivalence, when a test is adapted for use in another population.
- (18) Provide documentation for test users that will support good practice in the use of an adapted test with people in the context of the new population.

Statistical measures of comparability

The ITC establishes the need for statistical evidence to support various types of translation equivalence (ITC, 2017). Statistical evidence can be extremely useful to researchers who aim to establish construct and score equivalence among translated versions of a test.

At the item level, a common analysis employed to understand score equivalence is called differential item functioning (DIF). This statistical method compares groups of test takers and determines whether one set of test takers (e.g. English Language Learners or native English speakers) is more likely to correctly answer an item, despite comparable ability levels of the two groups. The key element here is that one group has a lower probability of answering an item correctly, despite the two groups being matched on their ability levels using an indicator such as the total test score.

While DIF can be used to understand group differences on any assessment, it is an especially useful tool in translation and adaptation because it can identify items that may have non-equivalence. If an item is identified as exhibiting DIF, an investigation of the item is warranted. For instance, an expert review of the DIF items may need to take place. The expert participants of a review should be familiar with the original and target languages, or both cultural contexts if applicable. These participants would examine both original and adapted DIF items to determine if the meaning of any words or phrases changed in the adaptation, or the equivalence of the terms used in both versions. Another type of investigation that can take place with DIF items is analysis of examinee cognitive processes through think aloud protocols (TAPs), in which students verbalize their thought processes either concurrently while responding to a test item or retrospectively after they have responded to an item. Examining cognitive processes can reveal important differences in translation or cultural contexts that impact students' abilities to demonstrate their knowledge (Ercikan et al., 2012). For instance, it may be determined that the translated item included words that differ from the target language in terms of difficulty, frequency of use, or overall meaning.

At the test level, construct comparability between forms may be examined through analyses such as exploratory or confirmatory factor analysis. This statistical method uses inter-item correlations to determine which items group together into "factors" or dimensions. Using this approach, it is possible to compare the dimensions of the original and translated test versions. Similarities across the two versions imply construct comparability, while dissimilarities may suggest a difference in the construct being measured by the two test versions. Exploratory factor analysis is performed separately for both groups and does not require that the factor structure be predicted prior to conducting the analysis, whereas confirmatory factor analysis does require a predicted factor structure, but may be used for multiple groups simultaneously.

Conclusions and future implications

Educational practices continue to evolve alongside technological innovations. Such advances have made translation more accessible than ever. For example, the proliferation of computer-based testing offers considerable opportunities to provide various forms of translated and adapted versions, including pop-up glossaries (Solano-Flores et al., 2019). Additionally, software programs that allow for immediate translation are numerous and often free to users. However, such accessibility also increases the danger of inaccurate or imprecise adaptations. Considering the many high stakes uses of test scores (e.g. graduation, special education placement), test developers should prioritize the implementation of best practices for translation and adaptation to promote the valid use of translated test scores.

This article opened with a description of the ever-increasing changes in migration that have been observed in the last 50 years, and its implications for more diverse schools and classrooms, as well as the general globalization of education. There is no indication that this trend will slow or pause; if anything, diversity in language and culture will only continue to intensify in schools. While exposure to diverse students based on language and culture offers many positive benefits to students, it is the responsibility of educators and researchers to ensure that assessment results are interpreted in a fair and valid manner.

The issues described in this article demonstrate how fairness comes into play when assessments are translated or adapted for diverse populations. Test developers and users may use this article to better understand the complex issues surrounding translation and adaptation in educational assessments. By being aware of these concerns, and following the practices described in the article, test developers and users can minimize construct irrelevant variance in assessment while promoting test fairness for ELL students.

People like to make comparisons. Sometimes, this urge to compare is sensible. For example, we can order objects by length or by weight. We may order students by perceived ability to read according to how reading is measured by a certain test. Scores from different assessments are sometimes compared sensibly; sometimes they are not. Rarely does a person consider using weight, one measure of size, as a surrogate for height, another measure of size. Yet that same person may be misled to assume that scores from any one educational assessment can be used as substitutes for scores from another assessment simply because they are said to measure the same thing.

The process that converts scores from different assessments to a common metric is called score linking. Simply because scores are on a common metric, however, does not mean they can be compared as if they measure the same attribute or construct. [Holland and Dorans \(2006\)](#) provided a framework for score linking that considered key aspects of the measurement process, including what is being measured by the tests to be linked, the trustworthiness of the scores produced by the tests, and the reason for linking the scores. Score linking can be divided into two fundamental categories: prediction and scale alignment, of which there are many subcategories, including score equating. The goal of prediction is to minimize errors for predicted scores on the dependent/criterion variable based on information from other predictor variables.

The goal of scale alignment is to transform the scores from two different tests onto a common scale. Scaling procedures are about 100 years old ([Hull, 1922](#); [Kelley, 1914, 1923](#)), yet scale alignment and score equating are often confused because the statistical procedures used for scale alignment can also be used to equate tests. As a consequence of this procedural identity, some view the distinction between equating and scale alignment (as well as distinctions among different types of scale alignment) as unnecessary because the numerical procedures are the same ([Livingston, 2014b](#); [van der Linden, 2013](#)). [Dorans \(2013\)](#) maintains that the distinctions made in the [Holland and Dorans \(2006\)](#) framework, and other frameworks, refer to the meanings that can be legitimately attached to the outcomes of the numerical operations, not to the procedures themselves. For example, it is easy to align distributions of height and weight in a specified population, and assign them to a common scale, e.g., largeness, such that a largeness unit of height is as far above the average height as a largeness unit of weight is above the average weight. That numerical alignment, however, does not mean that a largeness unit of height is *equal in meaning* to a largeness unit of weight.

It is important to distinguish between the subcategories of scale alignment because they are often seen as similar or identical when, in fact, they are not. The distinctions between different types of linkages are related to the similarities and differences between the tests as well as to the ways in which the linked scores are intended to be used and interpreted. The terms used for the various methods of score linking should have restricted meanings so that they may be used with precision. Understanding the distinctions

among these categories can promote appropriate score interpretations and discourage misinterpretations, misuse, and violations of professional practice.

The previous version of this chapter (von Davier, 2010) focused on different types of linking including item parameter linking in the context of item response theory (IRT). The emphasis of this chapter is on score equating where the goal is to produce interchangeable scores from different editions of the same test that are assembled from a common blueprint and administered under a standard set of measurement conditions. Equating adjusts for minor differences in the difficulties of alternate test forms so that interchangeable scores can be produced across the forms. Large representative samples of examinees, sound data collection practices, and appropriate methods are needed to produce equated scores on these test editions. Ideally, the tests should produce highly reliable scores as well.

The section **Score equating: a special case of scale alignment** addresses what distinguishes score equating from other forms of scale alignment. All methods for linking test scores include scores on two tests obtained by one or more samples of test takers, obtained via data collection methods as described in **Data collection designs** section, and one or more procedures for computing the transformation function, as described in **Procedures for equating scores** section. All methods of observed score equating specify a population of test takers to which the test linking is to be applied. Our focus is on observed score equating because true scores are unobserved and consequently of primarily theoretical interest only. The reality is that the observed score is all we can observe. Even sophisticated model-based scoring procedures that have theoretical true scores as their target only produce manifest observed scores, not latent unobservable scores, a point that is often not stated explicitly.

After describing score equating and what is needed to produce equated scores, in the **Score linkings that can be misconstrued as score equatings** section we address other forms of score linking that fail to achieve interchangeable scores even though they use the same procedures as those used for score equating. Unfortunately, equating-like interpretations are erroneously attached to these ersatz equating functions. In the last section we close with a discussion of best practices for score equating.

Score equating: a special case of scale alignment

Score equating is the strongest form of linking between the scores on two tests. Score equating may be viewed as a form of scale alignment in which very strong requirements are placed on the tests being linked. The goal of equating is to produce a linkage between scores on two test forms such that the scores from each test form can be used as if they had come from the same test. Among other things, the two tests built from the same blueprint or test specifications measure the same construct at the same or nearly the same level of difficulty and are administered under similar measurement conditions to produce scores with a similar degree of reliability.

Score equating involves scale aligning computations that link raw scores on a new form or edition of test X (the x 's) to those of an old form of test Y (the y 's). Then these equated raw scores from X , $e(x)$, are converted to a reporting scale. In practice, there is a scaling function that maps the raw scores of Y to the reporting scale, call it $S = s(y)$. The composition function, $S = s[e(x)]$, is the scaling function for X .

In practice, equating is necessary because of the inability to construct multiple forms of a test that are strictly parallel. Equating is used to fine-tune the test construction process. While impossible to achieve in practice, ideal equating can be approximated well with the type of sound equating practices promoted by Dorans et al. (2011).

There are four requirements that are widely viewed as necessary for a linking to be an equating. Those requirements are:

- a. **The Equal Construct Requirement:** The two tests should both be measures of the same construct.
- b. **The Equity Requirement:** It should be a matter of indifference to a test taker to be tested by either of the tests that have been equated.
- c. **Common Measurement Condition Requirement:** The test should be built to the same set of specifications and taken under the same measurement conditions.
- d. **The Symmetry Requirement:** The equating transformation for mapping the scores of Y to those of X should be the *inverse* of the equating transformation for mapping the scores of X to those of Y .

If requirements a, b and c hold, then the following consequences should hold:

- I. **Subpopulation Invariance:** The function used to link the scores of X and Y should be the same regardless of the choice of (sub) population from which it is derived.
- II. **Equal and High Reliability:** The test will produce scores that have equal and high reliability in any subpopulation taking the tests

Statements related to these appear in a variety of earlier and subsequent sources including Angoff (1971), Lord (1980), Petersen et al. (1989), Kolen and Brennan (2014), Holland and Dorans (2006), and Moses (2022). In practice, requirements (a) and (b) mean that the tests need to be built to the same content and statistical specifications. Requirement (c) acknowledges the important role that context plays in testing practice, as noted by Kolen and Brennan (2014). Consequences (I) and (II) may be used to explain why Lord (1980) noted that both (a) and (b) are necessary, and why we believe that (c) is also needed. If the two tests

measure different constructs, test takers will prefer the one on which they believe they will score higher, and some may prefer a less reliable measure than others. Dorans and Holland (2000) use consequence (I) to develop quantitative measures of equatability that indicate the degree to which equating functions depend on the subpopulations used to estimate them. Liu and Dorans (2013) explain how these measures and related measures of equatability can be used to assess the degree to which test scores are equatable. Requirement (b) is hard to evaluate empirically, and its use is primarily theoretical (Lord, 1980; Hanson, 1991). If consequence (II) does not hold then requirement (b) cannot be met. Brennan (2010) demonstrated analytically that equity can only be achieved with tests that produce highly reliable scores, confirming a hypothesis posited by Dorans and Walker (2007) that high reliability, rather than simply equal reliability, characterizes equated scores.

Data collection designs

To obtain the clearest estimates of test form difficulty differences, all score equating methods must control for differential ability of the test taker groups. Data collection strategies used for score equating strive to obtain equivalent groups, either directly or indirectly. Often, two different, non-strictly parallel tests are taken by different groups of test takers of unequal ability. Assuming that the samples are large enough to ignore sampling error, differences in the distributions of the resulting scores can be caused by either differences in the relative difficulty of the two tests or differences in the relative ability of the two groups taking these tests, or both. Difference in ability between the groups is a confounding factor that needs to be eliminated before the equating process can adjust for differences in test difficulty.

There are two different approaches for addressing the separation of test difficulty and group ability differences. The first approach is to use a common population of test takers. The other approach is to use an anchor measure of the construct being assessed by both X and Y.

When the same population of test takers takes both tests, we achieve direct control over differential test taker ability. In practice, it is more common to use two equivalent samples from a common population instead of identical test takers.

The second approach assumes that performance on a set of common items or an anchor test can quantify the ability differences between two distinct samples of test takers. The use of an anchor test allows for flexible data collection designs, but it comes with a cost. These designs employ procedures that make various assumptions that are not needed when the test takers are from the same population. Different methods make different assumptions and the various statistical adjustments for these group differences in ability can produce different results.

All procedures that follow, including those for samples from a common population, make a set of common assumptions needed to ensure that the linking can produce interchangeable scores. All samples are assumed to be random samples from their respective populations. In practice this may be only an approximation. In addition, all test takers are assumed to have had the opportunity to answer all the questions on one or both tests.

Because it is desirable for the statistical uncertainty associated with test equating to be much smaller than the other sources of variation in test results, it is important that the results of test equating be based on samples that are large enough to insure this. This fact should always be kept in mind when selecting a data collection design.

The single group (SG) and counterbalanced (CB) designs

The single group (SG) design is the simplest data collection design. In the single group design, all test takers in a single sample from population P take both tests. This design can provide accurate equating results with relatively small sample sizes. The SG design controls for differential group proficiency by having the same test takers take both tests. In using this design, however, it is necessary to assume that a test taker's score on the second test is unaffected by the fact that she or he has previously taken the first form.

To study whether order affects the results obtained with the SG design, the sample is sometimes randomly divided in half, and in each half sample the two tests are taken in different orders—X first and then Y or Y first and then X. This is the counterbalanced (CB) data collection design. The CB design contains both the SG and EG (described in [The equivalent groups design \(EG\)](#) section) designs within it.

The equivalent groups design (EG)

Typically, there is not enough testing time for every test taker to take more than one test. In the equivalent groups (EG) design, two equivalent samples are taken from a common population P, one is tested with X and the other with Y. The EG design avoids the issue of possible order effects that can arise in the SG design where each test taker takes both tests.

Sometimes test booklets are assigned randomly to groups, which is why this design is sometimes called the random groups design (Kolen and Brennan, 2014). While it does not require that the two tests have any items in common, this design can be used with items in common, which makes it an anchor test design (see next subsection). When sample sizes are large and tests forms are administered under secure conditions, the EG is the preferred data collection design.

Anchor test designs

In anchor test designs there are two populations, P and Q, with a sample of test takers from P taking test X, and a sample from Q taking test Y. In addition, both samples take an anchor test, A. von Davier et al. (2004) and Holland and Dorans (2006) call this the “Non-Equivalent groups with Anchor Test” (or NEAT) design. Kolen and Brennan (2014) and others refer to this as the “common-item nonequivalent groups design”.

The role of the anchor test is to quantify the differences in ability between samples from P and Q that affect their performance on the two tests to be equated, X and Y. The anchor A is usually, but not always, a shorter and less reliable test than the tests to be equated, but still measures the same construct as X and Y.

The relationship of A to X and Y can be of two different types. If A is a subset of items contained in both X and Y, then it is called an internal anchor test and scores on A are used in computing scores on the total tests. If A is a separately-timed test that each test taker takes in addition to one or the other of the tests being equated, then it is called an external anchor test.

The anchor test design contains two single-group designs within it. This structure underlies both anchor scaling (Holland and Dorans, 2006), and the chain equating methods to be discussed later. The anchor test design improves upon the flexibility of the EG design by allowing the two samples taking X and Y to be non-equivalent. Unlike the SG design, it does not require test takers to take both X and Y.

While the use of anchor tests may appear to be a minor variation of the previous data collection designs, the use of common items rather than common test takers involves new assumptions that are not necessary in the use of SG, EG, and CB designs. Some type of assumption is required to make up for the fact that X is never observed for test takers in Q and Y is never observed for test takers in P. For this reason, there are several distinct methods of scaling and equating tests using the NEAT design. Each of these methods corresponds to making different untestable assumptions about the missing data.

The difference between the anchor test design and the SG, EG, and CB designs can be thought of as the difference between observational studies versus experimental designs (Rosenbaum, 1995). The SG design is a repeated measures design with a single group and two treatments, the EG design is a randomized comparison with two treatment groups, while the CB design is a repeated measures design with a single group and counterbalanced order of treatments. In contrast, the common item design is an observational study where there are two non-randomized study groups that are possibly subject to varying amounts of self-selection. Liou et al. (2001) point out that the properly executed anchor test design produces missing data that are *missing at random* in the technical sense discussed in Little and Rubin (2002).

Unrepresentative or unmotivated samples undermine score equating; hence, special care should be taken to ensure that only members of the population of interest are included in the samples. If possible, the sample should be representative of the population as well. In addition, equating cannot be done effectively in small samples. The smaller the sample size, the more restricted is the class of stable equating methods. The single group (SG) design requires the smallest sample sizes, while the equivalent groups (EG) design requires the largest sample sizes to achieve the same level of accuracy, as measured by the standard error of equating (see Lord, 1950; Holland and Dorans, 2006). The anchor test designs require sample sizes somewhere in between those of the SG and EG designs; these requirements depend on how strongly correlated the anchor test is with the two tests to be equated and how similar the two populations are.

More extended discussions of data collection designs are given in Angoff (1971), Petersen et al. (1989), von Davier et al. (2004), Kolen and Brennan (2014), and Holland and Dorans (2006).

Procedures for equating scores

In this section, we will limit our discussion to observed score equating methods that use the data collection designs just described. Much of this section is an abridged version of the treatment provided by Holland and Dorans (2006). Consult Holland and Dorans (2006) for more complete treatments of observed score and true score procedures.

First, pre-processing steps are described. Next, observed score procedures are described, first for the common population case, and then for the case where anchor tests are needed to adjust for population differences before the test scores can be properly equated.

Some notation is used in this section. The *cumulative distribution function*, CDF, of the scores of test takers in the target population, T, on test X is denoted by $F_T(x)$, and it is defined as the proportion of test takers in T who score at or below x on test X. More formally, $F_T(x) = P\{X \leq x \mid T\}$, where $P\{\cdot \mid T\}$ denotes the population proportion or probability in T. Similarly, $G_T(y) = P\{Y \leq y \mid T\}$, is the CDF of Y over T. Cumulative distribution functions increase from 0 up to 1 as x (or y) moves from left to right along the horizontal axis in a two way plot of test score by proportion of test takers. In this notation, x and y may be any real values, not necessarily just the possible scores on the two tests. For distributions of observed scores such as number right or rounded formula scores, the CDFs are step functions that have points of increase only at each possible score (Kolen and Brennan, 2014).

Data pre-processing practices

Having collected the data, several steps should be taken to improve the quality of the data prior to score equating. These data processing steps deal with sample selection, item screening, and continuizing and smoothing score distributions.

Sample selection

Tests are designed with a target population T in mind. For example, admissions tests are used to gather standardized information about candidates who plan to enter a college or university. Test takers who are not part of this group can be removed from the equating analyses.

Statistical outlier analysis can be used to identify those test takers whose anchor test performance is substantially different from their performance on the operational test, i.e., the scores are so different that both scores cannot be plausible indicators of the test taker's ability. Removing these test takers from the equating sample prevents their unlikely performance from having an undue effect on the resulting equating function.

Checking that anchor items act like common items

The statistical properties of the common items should be evaluated to make sure they have not differentially changed from one test administration to the other. Internal common items are susceptible to context effects because they may be embedded within different sets of items in the two tests. Changes in widely held knowledge may also lead to changes in performance on anchor test items.

Simple plots of item difficulty values and other statistics may also be used to detect changes in items. It is important to check whether the difficulties of the common items are ranked in the same way across the old and new form samples. Item difficulty estimates from old and new form samples should correlate in the high 90s. That said, even correlations as high as the low 90s can still result in problematic score equatings. Differential item functioning methods may be used to compare the performance of the common items with the two test administrations treated as the reference and focal groups, and the total score on the common items as the matching criterion.

The need to continuize the discrete distributions of scores

Test scores are typically integers, such as number-right scores or rounded formula-scores. The equipercentile function defined below can depend on how the cumulative frequency distribution of X on T , $F_T(x)$, and Y on T , $G_T(y)$, are made continuous or "continuized". There are two methods of "continuization" of $F_T(x)$ and $G_T(y)$ that are in current use. [Holland and Dorans \(2006\)](#) treat two of these methods, the linear interpolation and kernel smoothing methods, in detail.

There are two primary differences between these two approaches to continuization. First, the use of linear interpolation results in an equipercentile function that is piecewise linear and continuous, resulting in functions that have kinks that some prefer to post-smooth ([Kolen and Brennan, 2014](#)). In contrast, kernel smoothing results in equipercentile functions that are very smooth (i.e., differentiable everywhere) and that do not need further post-smoothing. Second, the equipercentile functions obtained by linear interpolation always map the highest score on X into the highest score on Y and the same for the lowest scores (unlike kernel smoothing and the linear equating function). For more discussion on how the highest and lowest scores of two tests should be mapped, see [Petersen et al. \(1989\)](#), [Kolen and Brennan \(2014\)](#) and [von Davier et al. \(2004\)](#).

Presmoothing score distributions

Irregularities in the score distributions can produce irregularities in the equipercentile equating function that do not generalize to other groups of test-takers. Consequently, it is generally considered advisable to *smooth* the raw-score frequencies, the CDFs, or the equipercentile equating function itself ([Holland and Thayer, 1987, 2000](#); [Kolen and Jarjoura, 1987](#); [Kolen and Brennan, 2014](#); [von Davier et al., 2004](#); [Moses, 2011](#)). The purpose of this step is to eliminate some of the sampling variability present in the raw-score frequencies, in order to produce smoother CDFs for computation of the equipercentile function.

When presmoothing data, it is important to achieve a balance between a good representation of the original data and smoothness. Smoothness reduces sampling variability while a good representation of the data reduces the possibility of bias. The more parameters employed in the smoothing, the better the model will represent the original data, but the less smooth the fitted model becomes.

One way to presmooth data, proposed by [Lord \(1980\)](#), involves the use of an IRT model to pre-smooth a number-right score distribution prior to equipercentile equating. Let X and Y denote number-right scores for two tests with dichotomous test items. Using IRT, the conditional distributions of X and Y given the common latent ability, q , may be estimated. This computation exploits the assumption of local independence to compute $P\{X = x | q\}$ and $P\{Y = y | q\}$ as the probabilities derived from independent but not identically distributed conditional probabilities of 0/1 variables. See [Lord and Wingersky \(1984\)](#) and [Kolen and Brennan \(2014\)](#) for a detailed example and additional references. The estimated density function for the ability distribution over T , $f_T(q)$, may be approximated in various ways, and these results can be combined via numerical integration. The resulting estimated probabilities, $P\{X = x | T\}$ and $P\{Y = y | T\}$, are IRT model-based estimates of the original raw-score sample proportions, i.e., the proportion in the sample getting a score of x on X , or the proportion getting a score of y on Y . Thus, the estimates, $P\{X = x | T\}$ and $P\{Y = y | T\}$, may be regarded as a form of presmoothing of the two, unsmoothed sample score distributions. This is a use of an IRT model to presmooth the data, prior to continuization during equipercentile equating. Once the presmoothed estimated score probabilities are in hand, they may be continuized by either equipercentile-based linear interpolation or Gaussian kernel smoothing and used to produce a version of the equipercentile function, $Equi_{IRT}(x)$.

IRT observed score equating is seldom used in practice (see [Kolen and Brennan, 2014](#)). Compared to other presmoothing methods, it requires strong assumptions at the item level and is computationally more complex. Furthermore, there is no guarantee that these presmoothed estimates of the score distributions will reproduce the types of score frequencies found in real data. For this

reason, it is unlikely to be used except in research studies or very special situations with incomplete test data. For situations with data from complete tests, it is neither as efficient nor as flexible as the direct presmoothing of score frequencies using loglinear models, as advocated by [Holland and Thayer \(2000\)](#), [von Davier et al. \(2004\)](#) and others.

Smoothing score distributions works in moderately-sized samples, but does not help much with very small samples, especially when it is not clear how representative the sample is of the intended population. In these situations, one option may be to make strong assumptions about the equating function. The best practices solution to the small sample size problem may be to report raw scores and state that they cannot be compared across test forms. If the sample size suggested by consideration of standard errors is not achieved, raw scores could be reported with the caveat that they are not comparable to other scores, but that they could be made comparable when adequate data become available.

Observed score equating methods

Many procedures have been developed over the years for equating tests. [Holland and Dorans \(2006\)](#) considered three factors when attempting to develop a taxonomy of equating methods:

- (1) common population versus common item data collection designs,
- (2) observed-score versus true-score procedures, and
- (3) linear versus non-linear methods.

Because equating is an empirical procedure, it requires a data collection design and a procedure for transforming scores on one test form to scores on another. Linear methods produce a linear function for mapping the scores from X to Y , while non-linear methods allow the transformation to be curved. Observed-score procedures directly transform (or equate) the observed scores on X to those on Y . True-score methods are designed to transform the *true scores* on X to the true scores of Y . True score methods employ a statistical model with a test taker's true score defined as their expected observed test score based on the chosen statistical model. The psychometric models used to date are those of classical test theory and item response theory. [Holland and Hoskens \(2003\)](#) show how these two psychometric models may be viewed as aspects of the same model.

Observed score procedures for equating scores in a common population

As noted previously, there are three data collection designs that make use of a common population of test takers: the Single Group (SG), the Equivalent Groups (EG) and the Counterbalanced (CB) designs. They all involve a single population, P , which is also the target population, T .

We will use a definition of observed-score equating that applies to either linear or non-linear procedures depending on whether additional assumptions are satisfied. This allows us to consider both linear and non-linear observed-score equating methods from a single point of view.

The equipercentile equating function

The equipercentile definition of *comparable* scores is that x (an X -score) and y (a Y -score) are *comparable* in T if $F_T(x) = G_T(y)$. This means that x and y have the same percentile in the target population, T . When the two CDFs are continuous and strictly increasing, the equation $F_T(x) = G_T(y)$ can always be satisfied and can be solved for y in terms of x . Solving for y leads to the *equipercentile function*, $Equi_{YT}(x)$, that links x to y on T , defined by:

$$y = Equi_{YT}(x) = G_T^{-1}(F_T(x)) \quad (1)$$

In [Eq. \(1\)](#), $y = G_T^{-1}(p)$ denotes the inverse function of $p = G_T(y)$. Note that with discrete data, this relationship does not hold because for most x scores there is no y score for which the two cumulative distributions, one for x and one for y are exactly equal. Hence, with most applications, continuization steps are taken to make the data appear continuous (see [The need to continuize the discrete distributions of scores](#) section); different steps can yield different answers.

If [Eq. \(1\)](#) is satisfied, then $Equi_{YT}(x)$ will transform the distribution of X -scores on T so that it is the same as the distribution of Y -scores on T . Note that the target population T is explicit in the definition of $Equi_{YT}(x)$ ([Dorans and Holland, 2000](#); [von Davier et al., 2004](#); [Holland and Dorans, 2006](#)). In general, there is nothing to prevent $Equi_{YT}(x)$ from varying with the choice of T . For equating, we expect the influence of T to be small or negligible and we call the scores *equivalent*. In other kinds of linking, T can have a substantial effect and we call the scales *comparable in T*.

The linear equating function

It is sometimes appropriate to assume that the two CDFs, $F_T(x)$ and $G_T(y)$, have the same shape and only differ in their means and standard deviations. To formalize the idea of a common shape, suppose that $F_T(x)$ and $G_T(y)$ both have the form,

$$F_T(x) = K[(x - m_{XT}) / s_{XT}] \text{ and } G_T(y) = K[(y - m_{YT}) / s_{YT}] \quad (2)$$

where K is a CDF with mean 0 and standard deviation 1, m_{XT} and m_{YT} are the means of X and Y , and s_{XT} and s_{YT} are the standard deviations of X and Y .

When Eq. (2) holds, $F_T(x)$ and $G_T(y)$ both have the shape determined by K . In this case, it can be shown that the equipercentile function is the linear function, $Lin_{YT}(x)$, defined as

$$Lin_{YT}(x) = m_{YT} + (s_{YT} / s_{XT})(x - m_{XT}) \quad (3)$$

The linear function may also be derived as the transformation that gives the X-scores the same mean and standard deviation as the Y-scores on T. Both the linear and equipercentile functions satisfy the symmetry requirement (d) but reflect different definitions of comparable score scales (Kelley, 1923). This means that $Lin_{XT}(y) = Lin_{YT}^{-1}(x)$, and $Equi_{XT}(y) = Equi_{YT}^{-1}(x)$, i.e., equating Y to X is the inverse of the function for equating X to Y. In general, the function, $Equi_{YT}(x)$, curves around the function, $Lin_{YT}(x)$, such that the differences in these functions attributable to differences in the shapes of the CDFs fluctuate around 0 as the linear function approximates the first term of the expansion of the curvilinear function (von Davier et al., 2004, pp. 11–13).

The linear function requires estimates of the means and standard deviations of X- and Y-scores over the target population, T. It is easy to obtain these estimates for the SG and EG designs described in the Data collection designs section (see Angoff, 1971, or Kolen and Brennan, 2014). It is less straightforward to obtain estimates for the CB design, as noted by Holland and Dorans (2006).

Procedures for equating scores on complete tests when using common items

The anchor test design is widely used for equating scores because its use of common items to control for differential test taker ability gives it greater operational flexibility than the approaches using common test takers. Test takers need only take one test, and the samples need not be from a common population. However, this flexibility comes with a price. First, the target population is less clear-cut for the anchor test design—there are two populations, P and Q, and either one could serve as the target population. In addition, the use of the NEAT design requires additional assumptions to allow for the missing data—X is never observed in Q and Y is never observed in P. We use the term complete test to indicate that everyone in P sees all items on X and that everyone in Q see all items on Y. Our use of the term “missing data” is restricted to data that are missing by design. The assumptions needed to make allowances for the missing data are not easily tested with the observed data, and they are often unstated. As a result of this design, the equating of X and Y must be produced indirectly through the use of A (Holland and Dorans, 2006; Holland, 2007). We will discuss two distinct sets of assumptions that may be used to justify the *observed score* procedures that are commonly used with the anchor test design.

Braun and Holland (1982) proposed that the target population for the anchor test design, or what they called the *synthetic population*, be created by weighting P and Q. They denoted the synthetic population by $T = wP + (1-w)Q$, by which they meant that distributions (or moments) of X or Y over T are obtained by first computing them over P and Q, separately, and then averaging them with w and $(1-w)$ to get the distribution over T. There is considerable evidence that the choice of w has a relatively minor influence on equating results, for example, see von Davier et al. (2004). This insensitivity to w is an example of the population invariance consequence. The definition of the synthetic population forces the user to confront the need to create distributions (or moments) for X on Q and Y in P, where there are no data. In order to do this, assumptions must be made about the missing data.

Equating methods used with the anchor test design can be classified into two major types: *post stratification equating* (PSE) and *chain equating* (CE). Each of these types employs assumptions that assert that an important distributional property that connects scores on X or Y to scores on the anchor test A is the same for any $T = wP + (1-w)Q$, i.e., is population invariant.

Post-stratification equating methods

The PSE types of assumptions all have the form that the conditional distribution of X given A (or of Y given A) is the same for any synthetic population, $T = wP + (1-w)Q$. In this approach, we estimate, for each score on the anchor test, the distribution of scores on the new form and on the old form in T. We then use these estimates for equating purposes as if they had actually been observed in T. The PSE type of equating assumes that the relationship that generalizes from each equating sample to the target population is a conditional relationship. In terms of the missing data in the NEAT design, this means that conditional on the anchor test score, A, the distribution of X in Q (where it is missing) is the same as in P (where it is not missing). In the special case of an EG design with anchor test, $P = Q$ and the PSE assumptions hold exactly. When P and Q are different, the PSE assumptions are not necessarily valid, but there are no data to contradict them.

Chained equating methods

The CE assumptions all have the form that a linking function from X to A (or from Y to A) is the same for any synthetic population, $T = wP + (1-w)Q$. In this approach, we link the scores on the new form to scores on the anchor and then link the scores on the anchor to the scores on the old form. The “chain” formed by these two linkages links the scores on the new form to those on the old form. The CE type of equating approach assumes that the linking relationship that generalizes from each equating sample to the target population is an equating relationship. It is less clear for the CE assumptions than for the PSE assumptions what is implied about the missing data in the NEAT design (Kolen and Brennan, 2014).

In the special case of an EG design with anchor test, $P = Q$ and the CE assumptions hold exactly. In this special situation, the corresponding methods based on either the PSE or the CE assumptions will produce identical results. When P and Q are different, the PSE assumptions and CE assumptions can result in equating functions that are different and there are no data to allow us to contradict or help us choose between either set of assumptions.

Levine observed score equating method

In addition to the PSE and CE types of procedures, classical test theory may be used to derive an additional *linear observed-score* procedure for the NEAT design—the Levine observed-score equating function, $Lev_{YT}(x)$ (Kolen and Brennan, 2014). $Lev_{YT}(x)$ may be derived from two population invariance assumptions that are different from those that we have considered so far and that are based on classical test theory. Holland and Dorans (2006) use the form of classical test theory discussed in Holland and Hoskens (2003) to derive the Levine observed score equating function from two assumptions. To formalize the intuition that X, Y and A all measure the same construct, they assume their true scores are linearly related in a way that holds for all T, i.e., the three measures are congeneric.

Local linking

van der Linden and Wiberg (2010) propose an ability- or anchor-specific procedure for observed score equating in which the equipercentile linking function between test X and Y is defined at each level of an ability measure, such as the scores of anchor test A. This procedure has both theoretical and practical limitations as noted by Dorans (2013), and Holland (2013).

Best practices for common item equating

The following sections address issues that can make score equating challenging, especially when an anchor test design is employed. The quality and similarity of tests to be equated, choice of data collection design, characteristics of the anchor test in relation to the total tests, sample sizes and test taker characteristics, screening items and tests for outliers, and the choice of analyses all involve best practices that contribute to a successful equating.

The ideal design, in theory and in terms of best practice, is a large sample equivalent groups (EG) design with an external anchor test. If the anchor test is administered last, only the anchor test can be affected by possible order effects. A comparison of the distributions of the anchor test in the two (equivalent) samples then allows differential order effects to be identified; if they are substantial, the anchor test can be ignored, leaving a simple EG design, where no order effects are possible. If the anchor test is internal to the two tests, then context or order (e.g., item location) effects may arise and need to be dealt with.

In practice, however, large representative motivated samples that result from a random assignment of test forms to test takers are not always attainable. Reliability is not always as high as desired. Anchor tests may not be very reliable, especially internal anchors with few items. Anchors, especially external anchors, are not always highly related to the tests being equated. Lastly, tests are not always appropriate for the group that takes them. These issues often arise when best practices in design and data collection are not followed.

Best practices for the anchor test design

The anchor test design is often used because of the greater flexibility it provides. The role of the anchor test is to provide a common score that can be used to adjust for group ability differences before adjusting for test difficulty differences via equating. Scores from short anchor tests tend to have inadequate reliabilities, and consequently less than desirable correlations with the test scores. Low correlations may also result when the content of the anchor test differs from the test. Context effects can affect the comparability of anchor items. Anchors that are too hard or too easy for the target population produce skewed score distributions that are not helpful for equating.

Statistical procedures are needed to adjust for ability differences between groups when the anchor test design is used. Assumptions need to be made in order to make these adjustments; however, the assumptions may be flawed. In the case of the anchor test design, it is particularly important to employ multiple models as each model rests on different sets of assumptions. It is valuable to equate with several different models, including both linear and equipercentile models.

The equipercentile version of a particular method (say PSE) can be compared to the linear method version using the standard error of equating which describes sampling error and the difference that matters (DTM), an effect size that can be used to assess whether differences in equating functions have practical significance or are an artifact of rounding. Holland and Dorans (2006) describe the DTM, the standard error of equating and the standard error of the difference in equating or SEED. If the departures from linearity are less than the DTM and less than what would be expected due to sampling error, the linear model is often chosen on the grounds of parsimony because it is not sufficiently falsified by the data. Otherwise, the more general, less falsifiable, equipercentile model is selected.

With the anchor test design, the old and new form sample may perform very differently on the anchor test. Large ability differences on the anchor test tend to yield situations where equating is unsatisfactory unless the anchor is highly related to both tests to be equated. In this setting, different equating methods tend to give different answers unless the anchor test is strongly related to both the old and new tests. This divergence of results is indicative of a poor data collection design. The search for a single best model that could be employed universally would be unwise data analysis (Tukey, 1963).

Whether an equating test is an external anchor or an internal anchor also has an impact, as does the number of anchor tests and the type of score linking plan employed. For the observed score equating methods, described above, where the score on the anchor test plays an important role, it is often advised that the anchor test be a “mini-version” of the two tests being equated (Angoff, 1971).

Best practices for external anchors

The phrase external anchor usually refers to items that are administered in a separately-timed section and that do not count toward the test taker's score. For best practices, it is important to disguise the external anchor test so that it appears to be just another section of the test. This cannot always be achieved for tests that are composed of multiple distinct sections in which no one section contains all the item types. In these cases the section with the external anchor test is made to look like one of the test sections, preferably the one with the most item types represented.

Best practices for internal anchors

Items in an internal anchor test are part of the assessment and count toward each test taker's score. Internal anchor items are usually spread throughout the test. Because the items in an internal anchor test count toward the score, test takers are unlikely to skip them. On the other hand, once anchor test items have been used in the test administration of the old form, the items may become susceptible to security breaches and become known by test takers taking the new form to be equated. Security breaches are an unfortunate reality for many testing programs, and due diligence is required to prevent them or to recognize them when they occur.

Changes in the statistical properties related to item difficulty can occur with internal anchor tests due to context effects. Context effects can occur when common items are administered in different locations (e.g., common item 10 in one form is item 20 in the other form), or under different testing conditions (i.e., paper and pencil vs. computer delivered), or when they are adjacent to different kinds of items in the two tests. These effects are well documented (Leary and Dorans, 1985; Brennan, 1992; Harris and Gao, 2003). Mode of administration can also have an effect on the properties of an item, as noted by Gu et al. (2006), Keng et al. (2008), Kim and Huynh (2010) and Pommerich (2004, 2007).

Lack of invariance

An important property and consequence of score equating is that equating functions, to the extent possible, should be subpopulation invariant. These subpopulations should not be defined on the basis of the tests to be equated or the anchor test because the assumptions made by equating methods are sensitive to direct selection on the test or anchor.

The "same construct" and "equity" requirements are prerequisites for subpopulation invariance. One way to demonstrate that two tests are not equatable is to show that the equating functions used to link their scores are not invariant across different subpopulations of test takers. Lack of invariance in a linking function indicates that the differential difficulty of the two tests is not consistent across different groups. Note that subpopulation invariance is a matter of degree. In the situations where equating is usually performed, subpopulation invariance implies that the dependence of the equating function on the subpopulation used to compute it is small enough to be ignored.

Dorans and Liu (2009) and Liu and Dorans (2013) describe procedures that assess whether test scores on different forms that are expected to be used interchangeably are in fact interchangeable across different subpopulations. It uses the subpopulation invariance of linking functions across important subgroups (e.g., gender groups) to assess the degree of score exchangeability. These procedures focus on invariance at the reported score level. It is a basic quality control tool that can be used to assess whether a test construction process is under control, as can checks on the consistency of raw-to-scale conversions across test forms built to the same specifications (Haberman et al., 2008).

Score linkings that can be misconstrued as score equatings

Only tests that measure the same construct can be equated. Even though both height and weight are measures of size, height cannot be equated to weight. Likewise, a math test can be linked to a reading test, but it cannot be equated to a reading test. In this section, we discuss examples of score linkings that are not score equatings, but which might be misconstrued as score equating.

Dorans et al. (2007) use the linking taxonomy suggested by Holland and Dorans (2006) to examine score linkings that ranged from the relatively easy task of producing interchangeable scores on alternative versions of a test to the daunting challenge of aligning state standards with the National Assessment of Educational Progress (NAEP) scales. Since 2007, many more examples of attempts to link scores from different assessments have occurred, leading Moses (2022) to consider updating the framework provided by Holland and Dorans (2006) in an attempt to accommodate these various linkages.

Linkages across tests from different testing programs

The desire to compare scores from different assessments administered under different measurement conditions has always existed. Dorans et al. (2007) considered different types of linking that might be mistaken for score equating because they use data collection designs and statistical procedures associated with score equating. The interchangeability of scores associated with equating is not achieved, however, simply because certain numerical operations have been performed. Inferences that can be made from each of these types of linking are constrained by the features of the testing situation. Some prominent examples are discussed in this section.

Score linking is challenging when it involves two different tests, such as the SAT and ACT, that are produced by different assessment companies. Without a concordance, which provides a data-based path between the score scales of the two tests, the temptation might be to presume that the percentile ranks found in the norms tables for the two tests are comparable. That is rarely the case. For example, as reported in the summary of linkages in a joint cohort of ACT and SAT test takers between the ACT and the 2005 version of the SAT provided in Dorans (2020), a particular test taker in 2006 was more likely to achieve a score at the 75th percentile or above on the ACT than on the SAT because the SAT norms group was more able than the ACT norms group. Concordance tables attempt to address this problem.

The concordances between the ACT and the 2005 version of the SAT in a joint cohort of ACT and SAT test takers, summarized in Dorans (2020), provided linkages between ACT and SAT scores. Unlike equating, which produces the same link between scores across subgroups, concordances between scores from different tests such as the SAT and ACT can be subgroup dependent; for example, the linking between math score differed for males and females. Rather than replicate the design used in the earlier concordance based on a joint cohort of ACT and SAT test-takers, the College Board decided to update the ACT/SAT concordances through chains of concordances, some of which are based on self-selected examinees participating in administrations given prior to the official launch of the 2015/2016 version of the SAT (College Board, 2017, pp. 114–119). These concordances were criticized (Anderson, 2016a,b) and had to be replaced with direct ACT/SAT concordances that employed a superior collection design (College Board, 2018) similar to the design used jointly by ACT and the SAT programs to link the 2005 version of the SAT to the ACT (ACT, 2009).

Even when concordances are based on a single population of test takers, it is important to recognize that concordances are based on atypical subpopulations of their respective cohorts of test takers, namely those who take both tests. They may not work well where needed with test takers who take only one of the two tests. Lee and Brennan (2021) critique an attempt to use scale alignments of predicted scores to link the GRE and LSAT tests on a sample of matriculated law school students who took both tests. See Pommerich (2016) for an extensive treatment of the fairness issues associated with concordances.

There is often an interest in comparing performance across tests of different levels of difficulty for a given construct. Test scores are often compared across grades even though test content and test-taker groups differ. Vertical scaling is the term used to describe linkages that attempt to make these comparisons meaningful despite the changes in content and examinees that occur between grade levels, and despite the potential sensitivity of scaling results to differences in populations, grades and ages (Holland, 2007). Yen (2007), Briggs and Weeks (2009) and Kolen and Brennan (2014) address issues in vertical linking in greater detail.

Late last century the National Research Council published *Uncommon Measures* (Feuer et al., 1999). The motivation for that report was the debate in the late 1990s between those who favored voluntary national tests as a means of assessing the educational progress of students across the nation, and those who believed that statistical linkages among existing tests could be used to achieve that purpose. That volume examined the feasibility of linking the results of commercial and state tests to compare one student's achievement with national and international benchmarks as well as with those of students in other places. Feuer et al. demonstrated that it was not possible to link state assessments for reasons which were summarized by Thissen (2007, 2016). Dorans (2020) noted that the issues raised in *Uncommon Measures* (Feuer et al., 1999) remained relevant twenty years later.

Reardon et al. (2021) reported linkings of school district means on state tests to the NAEP scale, using statistical procedures that infer the district means on the state tests from published distributions of passing rates. Commentaries on Reardon et al. by Bolt (2021), Davison (2021), Moses and Dorans (2021) and von Davier (2021) re-emphasized longstanding cautions that the large variation in blueprints used by different state tests, as well as differences with NAEP with respect to content, administration conditions, stakes and examinee motivation are likely to make the interpretability of linking results restricted to comparing districts within states. Moses and Dorans (2021) provided empirical demonstrations that state-based linkings of district means from one test to another are not invariant across states even when the correlation of means within each state is very high.

Recent examples of concordances within testing programs

Recent events like the Covid-19 pandemic, repurposing of exams to meet multiple needs, competition for a dwindling supply of test takers, and innovative assessments have all contributed to a combination of increased demand for comparisons across different versions of the same test across disparate measurement conditions within testing programs. Responses to this increased demand for comparisons can produce linkings that may not be equatings.

Some testing programs have decided to shorten their tests. In order to be equated, tests need to produce equally reliable scores. A short test that produces erratic scores cannot be equated to a long test that produces very stable scores. Holland and Dorans (2006) used the term calibration to refer this type of linkage that does not produce interchangeable scores.

In addition to—or as an alternative to—shortening their tests, many large-scale testing programs transitioned from paper-pencil to online administration models in an effort to continue administering their tests with COVID-based closures to schools and testing centers. Camara (2020) described the risks of integrity, accuracy, reliability, validity and fairness of the scores produced from admissions and placement testing programs that administered online forms that were very different from their usual paper-pencil forms and standardized administrations. Linking across different modes of assessment depends on the similarity of the administration modes. Whereas the linking of linear digital administration forms to paper-pencil administration forms may be closer to equatings, the linking of adaptive digital administration forms to paper-pencil forms that involve not only different modes of administration but also different blueprints are less likely to be equatings (Eignor, 2007; Pommerich, 2016).

Sometimes, the administration of different tests in different modes or other different conditions of measurement involve groups that are not equivalent with respect to the constructs being measured and for which there are no common items. Baldwin and Clauser (2022) and Kim and Walker (2021) mention a variety of approaches to dealing with collateral quantitative information in place of common items. Some approaches to this problem involve using examinee background characteristics that are common to the administration groups to statistically weight or match the groups (Haberman, 2015; Livingston, 2014a; Wiberg and Branberg, 2015). These background characteristics measure something different than the tests being linked. When the background variables are weakly related to the scores to be linked, these approaches will not adequately adjust for group ability differences, as demonstrated in studies cited by Puhan and Kim (2022).

One option exercised in the absence of anchor test data may be to present a case for presuming that the scores from different modes or conditions are already aligned, and that no linking is needed. When users begin to compare the unlinked scores to the equated scores or when they assess whether different versions of the unlinked scores are comparable to each other; however, they may question the correctness of the properly equated scores as well as the unlinked scores. See Baldwin and Clauser (2022) for a discussion of interpretational difficulties that arose due to differences in unlinked and weakly linked scores for translated forms of the Psychometric Entrance Test (Beller, 1994).

Best practices for reporting score linkings that are not equatings

Best practices associated with unlinked or weakly-linked scores are to either avoid releasing scores based on questionable linkings and assumptions, or to release the scores by communicating both appropriate and inappropriate interpretations of those scores. For example, in the **Presmoothing score distributions** section, we recommended that the reporting of unequated raw scores for situations where the test administration sample sizes were too small for equating be accompanied with the caveat that the raw scores are not comparable to other scores, and that they would be made comparable when adequate data become available. Recommended communications might include cautions about limitations and potential misinterpretations of concordances within and across testing programs (Brennan, 2007; Pommerich, 2016). Other examples urging prudent interpretation of linkings between tests that do not measure the same thing and are designed for different purposes include the recommendation that linked GRE and LSAT scores not be used interchangeably for law school admissions without additional study (Lee and Brennan, 2021), and that linked district-means on NAEP and state tests have uses that should be restricted to within state comparisons (Moses and Dorans, 2021).

Summary

The comparability of measurements made in differing circumstances by different methods and investigators is a fundamental precondition for all of science. Psychological and educational measurement is no exception to this rule. Test equating techniques are those statistical and psychometric methods used to adjust scores obtained on different tests measuring the same construct so that they are comparable (Dorans and Holland, 2000, p. 281).

In high stakes settings, all test takers should be given an opportunity to maximize their performance under fair measurement conditions. Scores across different versions of the test should be as equivalent as possible. Some aspects of fairness lie outside the locus of control of test developers, such as opportunity to learn, quality of teaching, and test-taker motivation. Some components, however, can and should be controlled by the test developer and test administrator. Multiple versions of a test should be as parallel as possible. Score reliability should be large enough to justify the trust that users place in the scores. Test instructions should be clear and widely accessible to prospective test takers. Measurement conditions should be standardized and secure. Score equating procedures, when properly applied to reliable scores obtained under sound data collection conditions, can yield scores that may be treated as equivalent. The aspirations of score equating are worth achieving. When the same procedures are applied to unreliable scores from tests built to different specifications and administered under insecure, unstandardized conditions they fail to achieve the goal of score equating. Checking for equal and high reliability across versions of the test and the subpopulation invariance of the linking function are empirical checks on the quality of the linking results. These checks are essential for assessing the extent to which interchangeability and comparability are achieved, for communications about the quality and appropriate interpretations of linking results, and also for discouraging misinterpretations and misuse.

What is differential functioning?

Differential Functioning (DF) is a term derived from the concept of item bias which resulted in the development of Differential Item Functioning (DIF). Studies using this methodological approach date back to the 1960s, in attempt to determine why there were statistically significant differences, on average, between Minority and Caucasian students on achievement test performance, as measured by large-scale standardized tests (Angoff, 1993). The word bias can be defined as a divergence from expression or indication of truth. Statistically, it is a systematic distortion of a statistic, in this case the mean, for a factor that was not considered in its derivation. The concept underlying item bias is that the statistically significant differences found between Minority and Caucasian students on overall test performance was due to the additive impact of multiple items that were biased (Angoff, 1993).

Differential item functioning

Although the methodology of DIF was developed primarily for use on large-scale standardized tests, this approach can be used on any data collection tool for which an individual responds to multiple items that, taken as a whole, measure a construct. For example, DIF analyses could be conducted on surveys that measure self-esteem, self-efficacy, attitudes, beliefs, or personality. DIF analyses are conceptually based on the idea that some items are measuring one or more constructs in addition to the primary construct being measured; and that there are two or more groups that differ in their underlying distribution on these secondary dimension(s). If groups do not differ in their underlying distribution on the additional secondary measured by some items then DIF will not occur because, theoretically, the reason that items function differentially is based on the interaction between item and examinee characteristics.

Many educational and psychological tests are believed to multidimensional, meaning they measure at least two constructs. For example, research has demonstrated that mathematics items that ask examinees to explain something in writing, or to read complex passages, function differentially against less proficient writers and readers, respectively (Walker and Beretvas, 2001; Walker et al., 2008). In the first example the DIF analyses were conducting using writing proficiency as the grouping variable, because it was hypothesized that the secondary dimension measured by test items was writing ability. In the second example the DIF analyses were conducting using reading proficiency as the matching variable, because it was hypothesized that the secondary dimension measured by test items was reading ability. Then examinees were matched using total score on the mathematics items that did not require examinees to write, in the first case, or read, in the second case. In both cases the existence of DIF does not imply that these items are biased, since the addition of these item types increases the construct validity of the test, with respect to the National Council of Teachers of Mathematics (NCTM) Standards (NCTM, 2000). Therefore, the additional dimensions are considered *auxiliary* and the DIF is considered *benign* (Roussos and Stout, 1996a). It should be noted, however, that if only one score is reported, as opposed to reporting scores on mathematics ability and mathematical writing or mathematical reading ability, some

proficiency classification will be biased if a unidimensional *item response theory* model was used to create scale scores (Walker and Beretvas, 2001). This is particularly true for students whose overall test scores are near the cut points that determine proficiency classifications.

If the additional constructs measured by some items are unintended then item bias is said to exist (Ackerman, 1992; Zumbo, 1999). This type of DIF is sometimes referred to as *adverse* DIF while the additional constructs measured by some items are considered *nuisance* dimensions (Roussos and Stout, 1996a). For example, if a mathematics problem-solving test item also required examinees to understand how points are scored in the game of soccer then this item would function differentially against examinees who were not familiar with how points are scored in soccer. If it were also true that, on average, males were more familiar with these rules than females then this item would also function differentially against females. In both cases, examinees with an understanding of how points are scored in soccer have an unfair advantage in obtaining a correct answer to this test item, that has nothing to do with the construct of mathematical problem solving.

In DIF analyses, the group that is suspected to have an advantage due to the multidimensionality of some items is referred to as the reference group. Conversely, the group that is suspected to have a disadvantage is referred to as the focal group. There are many ways to test for DIF. However, in all cases the sign of the statistic obtained from the analysis indicates which group the item favors. Therefore, while researchers suggest that DIF analyses be conducted based on *a priori* hypotheses about the additional dimensions that are thought to influence performance (Gierl, 2005); it is also possible to conduct exploratory DIF analyses. The examples presented earlier were both conducted based on *a priori* hypotheses about the secondary dimensions. In the first example students that were classified as minimal or basic in writing composed the focal group, while those that were classified as proficient or advanced composed the reference group. A similar approach was taken for the second example presented earlier. Exploratory DIF analyses are routinely conducted during the test development process, when every test item is evaluated for the presence of DIF, using performance on all, or some, of the remaining test items as the matching variable. If exploratory DIF analyses are conducted, however; one should adjust the alpha level of the statistical test, to control for Type I errors, just as one would do when conducting many hypotheses tests for any other statistic.

Uniform and non-uniform DIF

DIF analyses can be conducted on both dichotomous and polytomous items. However, for the sake of simplicity we will focus only on dichotomous items in this section, knowing that all of the concepts presented can be generalized to polytomous items. There are two types of DIF that can occur, uniform and non-uniform. When *uniform DIF* occurs, the difference between the probability of responding favorably, or correctly, to an item is constant for all respondents in the reference group, regardless of their level of the underlying trait being measured. Fig. 1 illustrates an Item Characteristic Curve (ICC) for an item that is not functioning differentially. The y-axis reflects the conditional probability of endorsing, or correctly answering, this item. The x-axis reflects the latent trait scale. As Fig. 1 illustrates, when DIF does not occur there is no difference between respondents in the reference and focal group, in the conditional probability of endorsing, or correctly answering, an item. Fig. 2 illustrates uniform DIF. As the figure illustrates, the conditional probability of correctly responding to, or endorsing, an item is always higher for respondents in the reference group. In addition, the difference in the probability of correctly responding to this item is approximately constant across all ability levels for

Fig. 1 An ICC of an item when there is no DIF.

Fig. 2 An ICC of an item when there is uniform DIF.

Fig. 3 An ICC of an item when there is non-uniform DIF.

reference and focal group examinees. Conversely, when the difference in the probability of correctly responding to an item is not constant across all ability levels for the two groups, but rather depends on whether a respondent is high or low on the latent trait then *non-uniform DIF* is said to occur. In extreme cases, non-uniform DIF can result in *crossing DIF* as illustrated in Fig. 3. As the figure illustrates the conditional probability of endorsing or answering an item correctly is lower for respondents in the reference group with lower estimates of the latent trait and higher for respondents that are higher on the latent trait.

Differential bundle functioning

When multiple items on a measure are found to function differentially then Differential Bundling Functioning (DBF) is said to occur. DBF analyses should be conducted when one hypothesizes that the small DIF amount on single items are caused by the same secondary dimension because taken as a group they can be amplified to produce a significant amount of DIF across all the

items in a bundle (Nandakumar, 1993). In fact, many researchers suggest that DBF analyses based on substantive hypotheses be conducted whenever possible because they help us to understand *why* DIF occurs. This approach has great potential for helping researchers understand the cultural and cognitive reasons for the occurrence of DIF. It has been used to study the impact of language spoken, culture, accommodation status, reading ability, writing ability, and gender on test performance (Abbott, 2006, 2007; Banks, 2006; Finch et al., 2009; Gierl et al., 2003, 2001; Mendes-Barnett and Ercikan, 2006; Roussos and Stout, 1996b; Ryan and Chiu, 2001; Ryan and Fan, 1996; Walker and Beretvas, 2001; Walker et al., 2008).

An item bundle can be a group of items that have something in common that researchers believe constitute a secondary dimension. For example, one might hypothesize that all science items that require an examinee to mentally manipulate two- or three-dimensional figures will function differentially against females, since research has demonstrated that males, on average, are better at spatial visualization than females, on average. However, if a set of test items all share a common reading passage or graph then they should always be tested as a bundle because they are based on a common stimulus (Rosenbaum, 1988). Bundle can be created in a confirmatory manner, based on hypotheses and expert opinion, or in an exploratory manner, based on a statistical procedure such as factor or cluster analysis.

Differential test functioning

When DBF occurs, if all the items in the bundle are found to function against the focal group then Differential Test Functioning (DTF) is said to occur. In this case, depending on the number of items found to function differentially, one might hypothesize that statistically significant differences would be found on the mean of overall test scores between the two groups. This is not to be confused with impact, which refers to group differences on the primary construct measured by test items. Rather, DTF implies that there are group differences based on the secondary construct(s) measured by test items. On the other hand, when DBF occurs for both groups, meaning some items are found to function in favor of the focal while other items are found to function in favor of the referenced group, then cancellation can occur (Nandakumar, 1993). In this case, depending on the number of items that are found to cancel each other out, one would hypothesize that statistically significant differences would not be found on the mean of overall scores between the two groups.

In fact, research has demonstrated that there is a strong correlation between finding statistically significant differences between focal and reference group examinees on overall test score and the number of DIF items, as well as the magnitude of the DIF (Walker et al., 2012). However, this will only occur if the magnitude of the DIF is moderate and all items function differentially against the same group. Therefore, items that are found to function differentially should not automatically be removed from the test or measure. When the magnitude of DIF is negligible the aggregate of DIF items may not impact overall performance. Likewise, when cancellation occurs the impact of DTF on overall performance may be minimal. In these cases, automatically removing items that are found to function differentially may jeopardize the reliability and content validity of the test or measure. Conversely, when the magnitude of DIF amount is high and all items favor the reference group, the presence of DTF is problematic and items should be eliminated or rewritten.

Taken as a group, the concepts of DIF, DBF, and DTF are all different forms of DF. In all cases, the presence of any type of DF, be it adverse or benign, implies that there is not measurement invariance in the measure being used. This implies that the same overall score on the measure means different things for examinees, depending on what group they belong to which, in turn, implies that the validity of the test may be threatened.

Differential person functioning

Differential Person Functioning (DPF) is another conceptualization of differential functioning in which persons, as opposed to items, are investigated individually to determine if they perform similarly on two subsets of test items after controlling for item difficulty (Johanson and Alsmadi, 2002). In this procedure, item and person parameters are held constant, except for the person for whom DPF is being calculated. This procedure can be used to identify examinees who have cheated on a high-stakes exam, such as a certification exam, if a set of test items are administered to examinees that are known to be secure (O'Leary and Smith, 2017). Specifically, the performance of each individual examinee on the set of operational items that are suspected of being compromised is compared to their performance on the set of items that are known to be secure. If an examinee performs similarly on the operational items and the secure items, then an examinee would not be flagged for suspect behavior. If, on the other hand, an examinee performs well on the operational items but does poorly on the items that are known to be secure then they would be flagged for suspect behavior (Smith and Davis-Becker, 2011). This procedure can also be used to determine if an examinee performs equally well on different item formats or items in different content domains (Johanson and Alsmadi, 2002). It has also been referred to in the literature as person-fit statistics (Sinharay, 2016) and is the conceptualization behind the science of data forensics (Wollack, 1997).

Methods used to detect DIF

There are more than 20 different methods to detect DIF, all of which are conceptually based on the same general idea. Specifically, DIF detection methodologies statistically match two groups on total score or ability, the reference and focal group, that are created

based on a criterion variable (such as race or gender) and compare the performances of both groups on a particular item, after controlling for impact. Impact can be defined as true differences that exist between the two groups on the primary construct measured by non-DIF items. These methods differ in how they match respondents in the two groups—raw score or latent trait, how the groups are statistically equated or matched to control for impact; whether they can be used to test dichotomous or polytomous items; whether they are parametric or non-parametric tests; and, the statistical framework they are based on—categorical data analysis, item response theory, structural equation modeling, or latent class analysis. It should be noted that very few procedures allow one to test for DBF or DTF. Specifically, at the writing of this article, only SIBTEST and a specific application of Structural Equation Modeling (SEM) can be used to test for DBF or DTF.

Next, we explain, in greater detail, a representative subset of these methods.

Mantel Haenszel (MH)

Mantel–Haenszel (MH) is a non-parametric chi-squared test introduced by Mantel and Haenszel (1959) and later developed by Holland and Thayer (1988). In this method the total overall score on the test or measure is used as a matching variable.

The first step in calculating the MH test statistic is to form k subgroups of respondents for each possible total score. For example, on a ten-item multiple choice test there would be 11 groups of respondents, assuming that all possible scores from zero to ten were present in the data. Then a 2×2 contingency table is created, as shown in Table 1, for each of the k total scores to compare the performance of reference and focal group examinees on each individual item. The null hypothesis for this procedure is that the odds of responding correctly to item i are equivalent for respondents in the focal and reference groups for all k possible total scores on the measure.

$$\alpha_{MH} = \frac{\sum_j A_j D_j / T_j}{\sum_j B_j C_j / T_j} \quad (1)$$

Eq. (1) depicts the formula used to calculate the MH test statistic, which is used to estimate the odds ratio for reference and focal group respondents with a total score of j on item i . The value of the test statistic can range between 0 and infinity. A value of 1.0 indicates that one cannot reject the null hypothesis and thus there is no DIF. A value greater than 1.0 is indicative of DIF in favor of reference group while a value less than 1.0 is indicative of DIF in favor of the focal group. To simplify interpretation of the test statistic, Holland and Thayer (1985) proposed standardizing it by using a log transformation, thereby centering the value around 0. This transformed test statistic, $MH\Delta$ –DIF is depicted in Eq. (2).

$$MH\Delta - DIF = -2.35 \ln(\alpha_{MH}) \quad (2)$$

For the $MH\Delta$ –DIF statistic, a value of 0 indicates no DIF; negative values indicate DIF in favor of the reference group; and, positive values indicate DIF in favor of the focal group. Educational Test Service (ETS) developed guidelines for evaluating the effect size of this test statistic (Doran and Holland, 1993; Zwick, 2012). Specifically,

- Type A items—negligible DIF: items with $|MH\Delta - DIF| < |1|$ or $MH\Delta - DIF$ is not statistically significantly different from zero.
- Type B items—moderate DIF: items with $1 \leq |MH\Delta - DIF| \leq 1.5$, and statistically significant.
- Type C items—large DIF: items with $|MH\Delta - DIF| > 1.5$, and statistically significantly different from 1.

Type A items are considered to be DIF free items while Type B items should only be used if there are no equivalent items to replace them and Type C items should only be used if they are essential to meet test specifications (Zwick and Ercikan, 1989).

Utilizing MH to test for DIF is relatively easy and the results obtained from this DIF detection procedure are consistent with the results obtained using an IRT approach for DIF detection, if the 1-PL model is assumed (Holland and Thayer, 1988; Guo and Dorans, 2020); therefore, it is commonly used. However, one disadvantage of using this method is that it can only detect non-uniform DIF under some conditions (Masor et al., 1994). Another disadvantage of using this methodology is that the reference and focal groups are matched based on the number of correct responses on a test which is not an efficient matching variable when DIF is present in some items. Finally, this procedure cannot be used to test for DTF or DBF.

Table 1 Contingency table used to calculate the MH test statistic for item i .

	<i>Correct</i>	<i>Incorrect</i>	<i>Total</i>
Reference	A_j	B_j	$A_j + B_j$
Focal	C_j	D_j	$C_j + D_j$
Total	$A_j + C_j$	$B_j + D_j$	$T_j = (A_j + B_j + C_j + D_j)$

Note: A, B, C, and D corresponds to frequencies of each cell, j corresponds to the level of the total score.

SIBTEST

The SIBTEST procedure is also a nonparametric procedure for detecting DIF. SIBTEST was developed by [Shealy and Stout \(1993\)](#) in order to detect uniform DIF in dichotomous data and was further developed to test for non-uniform DIF and to detect DIF in polytomous items. In the SIBTEST approach, items are divided into two subsets, a matching subtest and the suspect subtest that is hypothesized to be functioning differentially. The suspect subtest can consist of a single item, when testing for DIF, or a bundle of items, when testing for DBF or DTF. The matching subtest consists of the rest of the items or a subset thereof. It is important that this matching subtest not include any items that are functioning differentially. Therefore, researchers have suggested using an iterative approach to purify the matching subtest by removing any items that are flagged for DIF in an exploratory analysis ([Gierl, 2005](#)). The null hypothesis tested using this procedure is expressed as:

$$H_0 : \beta = 0 \text{ vs. } H_1 : \beta \neq 0 \quad (3)$$

Using total test score on the matching subtest as a substitute for θ , an estimate of β is given by

$$\hat{\beta} = \sum_{k=0}^K P_k d_k \quad (4)$$

where P_k represents the proportion of examinees in that obtain a score of k on the conditioning valid subtest and $d_k = \bar{Y}_{Rk}^* - \bar{Y}_{Fk}^*$. $\bar{Y}_{Gk}^*$ is defined to be the average performance on the studied item for examinees in group G (i.e., the reference or focal group) who obtained a score of k on the conditioning subtest, corrected for bias by controlling for differences in items thought to be measuring the secondary dimension. SIBTEST also yields an overall statistical test for β . The test statistic, SIB, for evaluating the null hypothesis is

$$\text{SIB} = \frac{\hat{\beta}}{\hat{\sigma}(\hat{\beta})} \quad (5)$$

where $\hat{\sigma}(\hat{\beta})$ is the estimated standard error of $\hat{\beta}$. [Shealy and Stout \(1993\)](#) indicated that this test statistics asymptotically follows a normal distribution with mean of 0 and variance of 1 under the null hypothesis of no DIF.

[Roussos and Stout \(1996a,b\)](#) developed guidelines for interpreting the results obtained SIBTEST. Specifically:

- Type A items—negligible DIF: items with $|\hat{\beta}| < 0.059$
- Type B items—moderate DIF: items with $0.059 \leq |\hat{\beta}| < 0.088$
- Type C items—large DIF: items with $|\hat{\beta}| \geq 0.088$.

Poly-SIBTEST

Poly-SIBTEST is an extension of SIBTEST for polytomous items. In this procedure DIF-free subtest scores are used to represent the ability level of the latent trait of interest. The expected item scores can be estimated as:

$$ES_R(t) = \sum_{k=1}^m k P_{Rk}(t) \quad (6)$$

and

$$ES_F(t) = \sum_{k=1}^m k P_{Fk}(t) \quad (7)$$

where P_{Rk} and P_{Fk} are equal to the proportion of examinees in the reference group and focal group, respectively, that obtained a score of k on the studied item and have a subtest score of t .

A DIF index is estimated using an average difference of these adjusted scores, weighted by the proportion of examinees obtaining DIF-free subtest score equal to t . The estimated DIF index is represented by $\hat{\beta}$ where,

$$\hat{\beta} = \sum_{t=1}^T \left([ES_R^*(t) - ES_F^*(t)] \frac{N_R(t) + N_F(t)}{N} \right) \quad (8)$$

where T equals the maximum possible score on the DIF-free subtest, $N_R(t)$ and $N_F(t)$ are equal to the numbers of examinees obtaining DIF-free subtest score t from the reference group and the focal group respectively, and N is the total number of examinees. For large samples this DIF index, $\hat{\beta}$, can be assumed to be approximately normally distributed when the null hypothesis of no DIF is assumed ([Bolt, 2002](#)). Therefore, $\hat{\sigma}_{\beta}$ can be found using the following formula:

$$\hat{\sigma}_{\beta} = \sqrt{\sum_{t=0}^T \left[\frac{N_R(t) + N_F(t)}{N} \right]^2 \left[\frac{\hat{\sigma}_{Rt}^2}{N_{Rt}} + \frac{\hat{\sigma}_{Ft}^2}{N_{Ft}} \right]} \quad (9)$$

Then a test statistic, SIB, can be obtained by dividing the DIF effect measure by its standard error (Bolt, 2002):

$$\text{SIB} = \frac{\hat{\beta}}{\hat{\sigma}_{\beta}} \quad (10)$$

This test statistic can be evaluated against a standard normal distribution.

Logistic regression

Swaminathan and Rogers (1990) proposed the use of logistic regression for DIF detection with dichotomous items and it has been shown to be very effective (French and Miller, 1996; Swaminathan and Rogers, 1990; Zumbo, 1999). Like the MH procedure, the matching variable used is the overall total score on the test or measure. However, whereas MH considers the total score to be a categorical variable it is considered a continuous variable in logistic regression. When using logistic regression to test for DIF three different logistic regression models are fit to the data, a full model and two models that are nested within the full model. These models are depicted in Eqs. (11)–(13). In the full model the logit of the probability of a correct response to a particular item is predicted using total score, group (reference or focal), and the interaction of total score and group as depicted in Eq. (11). If this model is the best fit to the data then non-uniform DIF is present in the item being tested. This fit of this model can be compared to the fit of a nested model that eliminates the interaction term as depicted in Eq. (12). Specifically, if L_1 = the log Likelihood obtained from fitting the model depicted in Eq. (11) to the data and L_0 = the log Likelihood obtained from fitting the model depicted Eq. (12) to the data then $G^2 = -2[\ln(L_0) - \ln(L_1)]$, which reflects the difference between the deviance of the two models, can be used to determine if the interaction term is needed in the model. G^2 follows a χ^2 distribution with one degree of freedom, since one less parameter is estimated in this nested model. If G^2 is statistically significant then the interaction term is needed in the model, which implies that the item being tested has non-uniform DIF. If G^2 is not statistically significant then the interaction term is not needed. The next step is to determine if uniform DIF is present in the item being tested. To do so the difference between the Likelihood Ratio Tests obtained from fitting the model depicted in Eq. (12) (L_1) and Eq. (13) (L_0) is calculated to obtain a new G^2 statistic with one degree of freedom. If this test is statistically significant then the group variable is needed in the model, which implies that the item being tests has uniform DIF. If this test is not statistically significant, then the item being tested is not functioning differentially.

$$\text{Logit}(P(Y = 1)) = \beta_0 + \beta_1 \text{total} + \beta_2 \text{group} + \beta_3 (\text{total} * \text{group}) \quad (11)$$

$$\text{Logit}(P(Y = 1)) = \beta_0 + \beta_1 \text{total} + \beta_2 \text{group} \quad (12)$$

$$\text{Logit}(P(Y = 1)) = \beta_0 + \beta_1 \text{total} \quad (13)$$

Since power increases as sample size increases, very large samples can result in statistically significant G^2 statistics that are not practically significant. To determine the practical implication of including the interaction term and/or the group term in the model, changes in R^2 can be utilized (i.e., ΔR^2). In fact, Jodoin and Gierl (2001) developed guidelines for interpreting the results obtained when using logistic regression to detect DIF. Specifically,

- Type A items—negligible DIF: items with $\Delta R^2 < 0.035$
- Type B items—Moderate DIF: items with $0.035 \leq \Delta R^2 < 0.070$
- Type C items—High DIF: items with $\Delta R^2 \geq 0.070$

One of the advantages of using logistic regression to detect DIF, when compared to MH, is that it is not necessary to categorize the continuous matching variable and it is possible to model both uniform and/or non-uniform DIF (Zumbo, 1999). Another advantage of the logistic regression method is that it can detect both uniform and non-uniform DIF. However, one of the disadvantages, when compared to SIBTEST or Poly-SIBTEST, is that only single items can be tested. In addition, when the focal and reference groups have unequal ability distributions, and the sample size of at least one of the groups is small, there is a loss of power (Narayanan and Swaminathan, 1996).

It should be noted that several researchers have extended this methodology for use with polytomous items (French and Miller, 1996; Miller and Spray, 1993; Zumbo, 1999).

Methods based on item response theory (IRT)

There are several DIF detection methodologies that are based on the framework of item response theory including the Likelihood Ratio Test (Thissen et al., 1986, 1993, 1998), Raju's Area Measures (Raju, 1988, 1990), and Lord's χ^2 (Lord, 1980). These methods differ in terms of what is used to compare the performance of reference and focal group examinees on the studied item. The Likelihood Ratio Test compares the fit of two models—one in which all item parameters are assumed to be equivalent for reference and focal group examinees (L_0) and one in which item parameters for the items being studied are allowed to vary. The calculation of the test statistic, G^2 , is identical to what was done when logistic regression was used to test for DIF. The degrees of freedom for this test are equal to the number of parameters allowed to vary. Raju's area measure evaluates the magnitude of the area between two ICCs,

one for the reference group and one for the focal group. Specifically, a z-statistic is used to test the null hypothesis that the area between the ICCs is zero. Lord's χ^2 is used to compare the item parameters obtained from scaling the reference and focal groups separately.

These methods are similar in that they all must somehow control for impact, or true differences between the two groups on the primary construct measured by test items. Raju's area measures and Lord's χ^2 both require separate calibrations of the item parameters for the reference and focal group. Therefore, an equating procedure must be used to ensure that the item parameter estimates for the two groups are placed on the same scale prior to testing for DIF. The Likelihood Ratio Test utilizes a set of DIF-free anchor items, that is akin to the matching subtest used to test for DIF when using SIBTEST. They are also similar in that they can all be used to test for either uniform or non-uniform DIF and none of them can be used to test for DBF or DTF.

MIMIC model

The Multiple Indicators Multiple Causes (MIMIC) model (Joreskog and Goldberger, 1975) is rooted in the methodology of structural equation modeling (SEM) and can be used to test for DIF. In fact, it can be shown that the parameters obtained from fitting the MIMIC model can be easily transformed to the item parameters that would be obtained if IRT were used to scale the data or test for DIF (MacIntosh and Hashim, 2003). In general, SEM is a multivariate statistical approach that combines factor analysis and multiple regression to model the relationships between latent constructs and observed variables. When using a MIMIC model to test for DIF, the latent variable in the model is the underlying construct measured by the instrument. All items on the measure are modeled as indicators of the latent trait. This is the measurement part of the model and, in fact, is a confirmatory factor analysis. The structural part of the model includes regressing the grouping variable on the latent trait. This models impact, or true group mean difference on the latent trait. Items are tested for DIF by regressing the responses to the suspect item on the grouping variable. If group membership is a statistically significant predictor of responses to that item, after controlling for group mean differences on the latent trait, then it is functioning differentially. Similar to the use of the Likelihood Ratio Tests that have already been discussed, full and reduced models can be compared to determine which model is the best fit to the data.

MIMIC models can be used to test for uniform and non-uniform DIF with both dichotomous and polytomous items. They also are the only other procedure that can be used to test for DBF or DTF (Finch, 2012). Some of the other advantages of using the method to test for DIF are that the groups are matched based on a latent variable which is more accurate than using total score which include measurement error. It is also possible to model multidimensional items and test for multiple grouping variables at once, as opposed to only using two groups, using this methodology.

Latent DIF analysis

All of the DIF detection procedures that have been discussed utilize a manifest grouping variable, such as race or gender. However, mixture IRT models can be used to uncover latent grouping variables inherent in the data that are not measured (Cho et al., 2016). These models integrate IRT with Latent Class Modeling (LCM), which is a statistical procedure used to identify underlying groups, or clusters, of respondents that respond similarly to items on a measure. The models assume that respondents are from two or more latent populations that impact how they respond to the items. These different populations could be based on different problem-solving strategies on an educational test or different personality types on a psychological measure. They are simply variables that have not been directly measured, although it is possible that the latent classes that are identified really represent a manifest grouping variable. This will occur when there is a large overlap between the latent class identified by the model with an existing manifest grouping variable. There are four reasons why a researcher might want to consider a latent, as opposed to manifest, grouping variable: group membership is missing or one has no idea what group is of interest; group membership is unobservable or unmeasured, such as the examples provided earlier; the manifest variable is not reliable because there is heterogeneity in one or more groups, and the manifest variable may not be a valid indicator of true group membership (De Boeck et al., 2011).

How are DIF analyses used operationally?

Most educational testing companies periodically update the content of their tests. This is done by field testing items, which means they are administered but not used in the calculation of a respondent's latent trait or reported score. Field test items are then analyzed, with respect to their difficulty, discrimination, and whether they are functioning differentially to determine which items should be operationalized. Items should be tested for both uniform and non-uniform DIF. If an item is found to have C level DIF then a panel of experts, in the content area being assessed by the test, is convened. For instance, if the item is related to language proficiency and differentially functioning against to males, then the panel must be diverse, with respect to gender, country of origin, and language spoken, and must not be familiar with the item, as would be the case if they were involved in the writing of the item. Panelists discuss potential reasons for the occurrence of DIF and are asked to come to a consensus decision about *why* the item might be functioning differentially. If they can come up with a reason as to why they all believe that the item is functioning differentially then the item is rewritten and field tested again, to determine if the changes have resulted in a DIF-free item. If they cannot come up with a reason as to why the item is functioning differentially then the item should not be used operationally unless there is a very

strong rationale. This decision should be based on the direction and magnitude of the DIF; whether or not there is cancellation, which occurs when some items function in favor of the reference group and other function in favor of the focal group, and the test specifications, to ensure that content validity will not be compromised.

Why are DF analyses an important part of test development and validation?

DF analyses are an important part of test development and validation because they help to ensure that scores obtained from educational tests and psychological measures are unbiased and reflect the same construct for all examinees or respondents. As previously described, DF analyses are routinely used by test developers and they are equally as important in the development of psychological assessments. It is equally vital that equivalent scores obtained from a measure of anxiety or an interest inventory reflect the same construct for all respondents, regardless of gender, race, or ethnicity, as it is for equivalent scores from an educational assessment to reflect the appropriate construct. This verification represents an important aspect of the test validation process, in terms of defining the construct or constructs that are being assessed. Thinking carefully about what test items may be measuring, in terms of the primary construct an assessment is designed to measure as well as any additional constructs that may be measured by test items, is critical. Moreover, how groups of examinees may differ in their underlying distribution on any supplemental dimensions measured by items can allow one to come up with testable hypotheses that can be assessed in a confirmatory manner to better understand the underlying structure of a psychological measure.

Practical considerations

With so many methods available for evaluating items for DIF, the reader may be wondering which one to use. As is often the case, there is no simple answer to this question. Specialized software is needed for almost all procedures discussed, which may be a reason for not selecting a particular method. Exceptions to this are the MH procedure and logistic regression, which can be conducted using any standard statistical software program. Some of the procedures can only be used to test for uniform DIF, which may be a reason for not using them. While all methods work better with larger sample sizes which provide better estimates, some, such as those based on IRT, require large samples for estimation. Some of the procedures can test for DBF and DTF which may be a reason for selecting them for use. In general, one should choose the method that is most aligned with their hypothesis, the nature of data (dichotomous vs. polytomous), and research questions posed. In addition, given that each method differs, with respect to how they ensure that the results are not biased by impact, it is advisable to use more than one method to cross-validate findings.

As stated previously, all methods work better with larger sample sizes. This naturally leads to the question of how many respondents are needed to conduct DIF analyses. Once again, the answer is complicated. One thing that is known to affect type I error is having comparable sample sizes in both the reference and focal group (Miller and Oshima, 1992). Balanced samples are typically better than unbalanced samples when it comes to type I error and power. With unbalanced designs, it has been suggested that multiple random samples be drawn from the larger group and multiple analyses be conducted with the smaller group to cross-validate results, with unbalanced sample sizes (Sireci and Rios, 2013). However, even for small focal group sample sizes, as may be the case in practice, adequate power is achieved if the sample size of the reference group is large, when Mantel-Haenszel is used to test for DIF (Paek and Guo, 2011). In general, it has been suggested that the focal group consist of at least 200 during the test assembly phase and at least 300 during the item analysis phase (Zwick, 2012). Non-parametric procedures require smaller sample sizes than do parametric procedures. Typically, when using IRT based methods it is recommended that each group have at least 500 respondents (Narayan and Swaminathan, 1996). For non-IRT based methods, it is recommended that each group have at least 200 respondents, if the measure has at least 20 questions, and at least 300 in each group if the measure has less than 20 items (Scott et al., 2009).

One thing that has already been touched on, is the importance of having a DIF-free subtest score, when using this as the matching variable. This implies that one should not simply utilize a respondent's total score on all remaining test items, that are not being tested for DIF, as the matching variable. It is possible that some of these items are actually functioning differentially, even if they are not suspected of doing so. Therefore, it is suggested that all items that are found to be functioning differentially, when conducting single-item analyses, be removed from the matching subtest score and the analyses be re-run.

Glossary

Goodness of fit index A numerical summary of the discrepancy between the observed data values and the values expected under a statistical model

Goodness of fit statistics A goodness of fit index with known sampling distribution that may be used in statistical hypothesis testing

Absolute goodness of fit The discrepancy between a statistical model and the data generating mechanism

Relative goodness of fit The discrepancy between two statistical models

Introduction

The **goodness of fit** (GOF) of a statistical model refers to the extent to which a statistical model captures the data generating mechanism. When more than one model is under consideration **model selection** is necessary. Thus, goodness of fit refers to assessing the discrepancy between the model and the data, whereas model selection refers to assessing the discrepancy between two models. GOF is often referred to as model-data fit, or absolute fit. Model selection is often referred to as relative model fit.

Two different perspectives exist regarding goodness of fit and model selection. One perspective views modeling as describing the data (Cudeck and Henly, 1991; MacCallum, 2003). From this perspective, all models are simply approximations to real life phenomena (“all models are wrong”) and the researcher’s aim is to choose the model that provides the “best” approximation to the data generating process. From this perspective, it makes sense to focus on model selection. An alternative perspective views modeling as estimating structural or “causal” relations even when data is observational (Pearl, 2009; Bollen and Pearl, 2013). From this perspective, inferences are to be as precise and valid as possible, and the focus is on model fit.

Goodness of fit vs. model selection

The goodness of fit vs. model selection distinction, and how they are intertwined, can be illustrated by considering a simple regression model $y = \beta_0 + \beta_1 x + \varepsilon$ with homoscedastic errors. The model’s R^2 is a model selection statistic, which can be used for instance to choose between (a) the linear regression model $y = \beta_0 + \beta_1 x + \varepsilon$, and (b) a mean-only model $y = \beta_0 + \varepsilon$. We illustrate this in Fig. 1, in which R^2 can be used to successfully select between both models in all instances. R^2 is **not** a goodness of fit statistic. We also illustrate this in Fig. 1, where interpreting R^2 as a goodness of fit statistic would lead us to conclude that the model fits well in (b) but

Fig. 1 Goodness of fit and model selection for a simple linear regression model.

not in (c), while it fits excellently in (c) but not in (b). Rather, goodness of fit in linear regression is usually assessed using plots, although if repeated observations are available for each value of x , a goodness of fit test may be performed. This test statistic is usually referred to in the regression literature as lack of fit test (Weisberg, 2005). Only after the fit of the regression model has been established, R^2 , a model selection statistic, is applied and interpreted.

In applications, we recommend that both goodness of fit assessment and model selection be performed. When fitting several models to a dataset, after determining that more than one model fits well, model selection must be performed. Alternatively, after selecting the best fitting model, some evidence of the fit of the model must be obtained. When model selection is performed, but goodness of fit assessment is not, the resulting model may fit the data rather poorly, and lead to misleading substantive conclusions (Maydeu-Olivares, 2017b). When goodness of fit assessment is performed but no alternative model is considered (i.e., no model selection), the resulting model may overfit the data and not cross-validate well.

In some applications different conclusions may be reached if a goodness of fit or a model selection perspective is adopted. This is illustrated in Fig. 1D. If a pure model selection perspective is adopted, correctly concluding that the mean-only model is to be selected over the linear model is all that matters. This is consistent with considering models as approximations. From a goodness of fit perspective, because we observe some non-linearity and heteroscedasticity, it may be concluded that neither the linear regression model nor the mean only model capture the data generating mechanism, and that a better model must be sought.

Model fit in factor analysis and structural equation modeling

Moving from assessing the fit of a single linear equation to assessing the fit of a set of linear equations we should apply the same principles. Plots are to be used to assess model fit for each model equation. When latent variables (i.e., common factors) are involved, a complication arises as latent variable values are not observed, and they must be estimated, i.e., factor scores must be used (Bollen and Arminger, 1991).

When a system of equations is fit, residual means and covariances (or correlations) provide an additional procedure to assess the fit of the model. For instance, a test of the suitability of the restrictions imposed on the covariance among two variables can be obtained using a z -statistic for the residual covariance (Maydeu-Olivares and Shi, 2017),

$$z_{ij} = \frac{s_{ij} - \hat{\sigma}_{ij}}{SE(s_{ij} - \hat{\sigma}_{ij})}, \quad (1)$$

where s_{ij} denote the sample covariance between variables i and j , $\hat{\sigma}_{ij}$ denotes the covariance predicted by the model, and $SE(\bullet)$ denotes standard error.

Often, some residual means and covariances are zero by construction and they cannot be tested. For instance, in a multivariate regression model all residual means and residual covariances are zero by construction and, as a result, they do not provide information about the fit of the model. As another example, researchers often use structural equation models (SEM) that do not impose restrictions on the intercepts of the model equations (intercepts are freely estimated). In this case, residual means are zero by construction, they are known to be zero before any data is gathered, and therefore z statistics cannot be computed.

To control for multiple testing across all z statistics, overall goodness of fit tests are used.

Overall goodness of fit statistics

Historically, the likelihood ratio test statistic has been the most widely used overall goodness of fit test statistic. When no restrictions are imposed on the means of the observed variables (aka covariance structure models), the likelihood ratio test can be written as

$$T_{LR} = N \{ \ln |\hat{\Sigma}| - \ln |S| + \text{tr}(\hat{S}\hat{\Sigma}^{-1}) - n \}, \quad (2)$$

where S denotes the sample covariance matrix among the n observed variables, $\hat{\Sigma}$ denotes the covariance matrix expected under the model evaluated at the values of the estimated model parameters, and N denotes sample size. If the observed data follows a multivariate normal distribution, the distribution of the likelihood ratio test statistic can be approximated by a chi-square distribution in large samples. Because of its popularity, T_{LR} is commonly referred to as *the* chi-square test in the factor analysis and structural equations modeling literature.

However, T_{LR} should not be used in small samples, nor when data departs from normality. Recent research has also shown that p -values obtained using this test are too small when all assumptions are satisfied but the number of variables exceeds 20 or 30, even in very large samples (Moshagen, 2012). As a result, well-fitting models will be rejected when the number of variables is large.

T_{LR} is not the only overall test statistic for structural equation modeling that follows a chi-square distribution. For instance, Browne (1974, 1982, 1984) proposed a test statistic that for covariance structure models can be written as

$$T_B = N \hat{\mathbf{e}}' \hat{\mathbf{C}} \hat{\mathbf{e}}, \quad \mathbf{C} = \mathbf{\Gamma}^{-1} - \mathbf{\Gamma}^{-1} \Delta (\Delta' \mathbf{\Gamma}^{-1} \Delta)^{-1} \Delta' \mathbf{\Gamma}^{-1}. \quad (3)$$

In (3), $\hat{\mathbf{e}} = \mathbf{s} - \hat{\boldsymbol{\sigma}}$ denote the residual covariances transformed from a matrix layout to a single vector, $\mathbf{\Gamma}$ denotes the covariance matrix of the sample covariances in large samples, and Δ is a matrix of derivatives of the population covariances with respect to the model parameters. There are two variants of this statistic, depending on how $\mathbf{\Gamma}$ is computed: under normality assumptions, $T_B^{(NT)}$, or under the very general asymptotically distribution free (ADF) assumptions, $T_B^{(ADF)}$ (Browne, 1982). In both cases, p -values can be obtained in large samples using a chi-square distribution. We note that under normality assumptions and when maximum likelihood is used to estimate the model parameters, (3) simplifies to $T_B^{(NT)} = N \hat{\mathbf{e}}' \hat{\mathbf{\Gamma}}_{NT}^{-1} \hat{\mathbf{e}}$, where $\mathbf{\Gamma}_{NT}$ denotes $\mathbf{\Gamma}$ computed under normality assumptions.

$T_B^{(NT)}$ is a direct competitor to T_{LR} (both assume normality), whereas $T_B^{(ADF)}$ provides a goodness of fit test robust to non-normality. Unfortunately, very large sample sizes are needed for the p -values of $T_B^{(ADF)}$ to be accurate, and sample size requirements increase as the number of observed variables increase (Curran et al., 1996). As a result, $T_B^{(ADF)}$ should only be used in small models and very large samples.

An alternative way to obtain p -values when data is non-normal was proposed by Satorra and Bentler (1994): adjust a test statistic for normally distributed data by its asymptotic mean (or by its asymptotic mean and variance) so that it agrees in mean (or in mean and variance) with a chi-square distribution. Mean and variance corrected statistic provide more accurate p -values than mean corrected statistics (Maydeu-Olivares, 2017a), and even outperform uncorrected statistics when their assumptions are met (i.e., under normality).

The current standard to assess the overall goodness of fit of a structural equation model is the likelihood ratio test statistic T_{LR} , suitable for normally distributed data, and its mean (or mean and variance) adjustment suitable for non-normal data, $\bar{T}_{LR}$ and $\bar{\bar{T}}_{LR}$, respectively. However, Browne's test statistic computed under normality, $T_B^{(NT)}$ can also be adjusted by its mean (or mean and variance), leading to $\bar{T}_B^{(NT)}$ and $\bar{\bar{T}}_B^{(NT)}$. Hayakawa (2019) has shown that $T_B^{(NT)}$ provides more accurate p -values than the likelihood ratio test statistic, T_{LR} . In particular, $T_B^{(NT)}$ appears to overcome the overrejection problem of T_{LR} when the number of observed variables is large relative to the sample size T_{LR} . Hayakawa's results strongly suggest that Browne's statistic (3), not the likelihood ratio statistic (2), possibly with a Satorra-Bentler adjustment to account for non-normality, should be the statistic of choice to assess the overall goodness of fit test in for SEM and other multivariate latent-variable models.

Identifying the source of misfit and model modification

Overall goodness of fit statistics are summary measures of the residual means and covariances. For instance, Browne's statistic (3) is a weighted average of residual covariances. As a result, before interpreting an overall test of model fit it is necessary to examine whether there is any outlying residual means/covariances that unduly inflates the value of the statistic. Also, residuals means and covariances should be inspected to identify parts of the data that are not well fit by the model. In so doing, it is necessary to consider that multiple tests are performed. The simplest approach to deal with multiple testing is to apply a Bonferroni correction to the critical value used in the z -statistics (1), but more accurate procedures are preferable (Benjamini and Hochberg, 1995; Thissen et al., 2002). In poorly fitting models, inspection of residual means and covariances may suggest the source of model misfit. However, often modification indices are more useful to this aim.

Models impose restrictions, implicitly or explicitly, on their parameter values. Examples in factor analysis are setting a factor loading equal to zero, or the correlation between the errors of two equations equal to zero. Modification indices may be used to test those restrictions one at a time. These are *score-test* statistics (Buse, 1982) with one degree of freedom that contrast the fitted model (where this parameter is set to a fixed value) against a model in which this parameter is estimated. Together, the modification index (i.e., the value of the test statistic), the expected parameter change, and the power of the test enable researchers to investigate whether there is a small misspecification for which the test statistic is very sensitive, or a large misspecification that the test statistic is not sensitive enough to identify (Saris et al., 2009).

Goodness of fit indices

As the number of variables being modeled increases, so do degrees of freedom (intuitively, ways that the model can be wrong), and it becomes increasingly difficult to find a well-fitting model (Maydeu-Olivares, 2017b). In these situations, researchers resort to the use of goodness of indices, coupled with cutoff criteria that have been offered in the literature (Hu and Bentler, 1999) and use them as test statistics: models are retained if they meet the cutoff criteria, and rejected otherwise (Barrett, 2007). The most widely used goodness of fit indices are probably the Root Mean Squared Residual (RMSEA: Browne and Cudeck, 1993), the Standardized Root Mean Residual (SRMR: Jöreskog and Sörbom, 1988), the Tucker-Lewis index (TLI: Tucker and Lewis, 1973), and the Comparative Fit Index (CFI: Bentler, 1990).

Letting t be the number of residual covariances in a model, the sample SRMR is

$$\widehat{SRMR} = \sqrt{\frac{1}{t} \hat{\mathbf{e}}' \hat{\mathbf{G}}^{-1} \hat{\mathbf{e}}} = \sqrt{\frac{\sum_{i \leq j} (s_{ij} - \hat{\sigma}_{ij})^2}{s_{ii} s_{jj}}}, \quad (4)$$

where $\hat{\mathbf{G}}$ is a diagonal matrix with elements $s_{ii} s_{jj}$. The SRMR can be approximately interpreted as the average residual correlation. In turn, the sample RMSEA is

$$\widehat{RMSEA} = \sqrt{\max\left(\frac{T - df}{N \times df}, 0\right)}. \quad (5)$$

where df refers to the degrees of freedom of the model, and T denotes the chi-square statistic used to assess whether the model fits exactly in the population (generally the likelihood ratio test statistic). When Satorra-Bentler corrected statistic is used to account for non-normality, (5) needs to be adjusted accordingly (Savalei, 2018).

The SRMR and RMSEA assess the degree of absolute fit of a model. The closer the values of the SRMR and RMSEA to zero, the better the fit of the model. The RMSEA includes a degrees of freedom adjustment, to penalize models with too many parameters, whereas the SRMR does not. In turn, the sample TLI and CFI are relative model fit indices. They involve two models, M_0 and M_1 , where the former is more restrictive. The sample TLI and CFI are

$$\widehat{TLI} = \frac{\frac{T_0}{df_0} - \frac{T_1}{df_1}}{\frac{T_0}{df_0} - 1}, \quad (6)$$

$$\widehat{CFI} = \frac{(T_0 - df_0) - (T_1 - df_1)}{T_0 - df_0}. \quad (7)$$

where T_0 and T_1 are the chi-square statistics, of each model; and df_0 and df_1 are their degrees of freedom. Both the CFI and TLI are normed to lie between 0 and 1. Larger values indicate better fit. Almost invariably the CFI and TLI are used to compare the fitted model against a model that assumes that variables are uncorrelated. When used in this fashion, TLI and CFI values are very large.

Consider using goodness of fit indices to determine whether to retain a one factor model when the data generating model involves two factors. A one factor model is close to the two factor model when the inter-factor correlation is very high (say 0.9), but it provides a poor approximation when the correlation is low (say 0.2). As a result, we would like the goodness of fit indices to suggest retaining a one factor model in the first case, but not in the second case, regardless of sample size, model size (number of variables), and factor loading used to generate the data. We illustrate in Fig. 2, taken from Ximénez et al. (2022), that this is not the case. In this figure we have plotted the population value and average sample behavior of the RMSEA and CFI across a number of

Fig. 2 Population and average sample CFI and RMSEA when fitting a one factor model to two factor model data

Note: ρ denotes the correlation between the factors, N is sample size. Data were generated so that all items had a common standardized factor loading (0.30, 0.60, and 0.90), 1000 replications were obtained per condition, pop is the population values for each index, and the red solid line corresponds to [Hu and Bentler's \(1999\)](#) cutoff for each index. Models are to be retained if estimated CFI is above the suggested cutoff, and if estimated RMSEA is below the suggested cutoff.

conditions. We have also included in this figure the cut-off values suggested by [Hu and Bentler \(1999\)](#). As we see in this figure, these cutoffs would lead to reject that a one factor model is a close approximation to a two-factor model with correlation 0.9 when sample size is small, the number of observed variables is large, and factor loadings are strong. Two findings are particularly striking in [Fig. 2](#): (a) the effect of sample size on the average behavior of the CFI is considerably larger than on the average behavior of the RMSEA, and (b) with large number of variables (e.g., $n = 72$) and small samples ($N \leq 200$), the CFI would lead us to conclude, on average, that a one factor model does not fit closely even when it fits exactly (i.e., $\rho = 1$). These findings are due to the fact that the RMSEA estimate (5) was formulated to be an unbiased estimator of the RMSEA population parameter, whereas the CFI estimate (7) is not an unbiased estimate of the CFI parameter; it is simply the sample counterpart of the population parameter. When an unbiased estimator of a goodness of fit parameter is used, cutoff values can be determined using the parameter, as sample size plays no role in the average behavior of the index. This can be seen in [Fig. 3](#), where we display the behavior of the sample SRMR (4), along with its unbiased counterpart ([Maydeu-Olivares, 2017b](#)).

Cutoff criteria for goodness of fit indices (SRMR, RMSEA, CFI, etc.) to distinguish between close and non-close fitting models are (a) to be put forth at the population level, (b) an unbiased estimator is to be used so that the average behavior of the estimate matches the behavior of the parameter, and (c) a confidence interval for the population value is needed to take into account sampling variability. Also, population cutoff criteria probably need to be adjusted to take into account extraneous factors, so that the population index just reflects misfit. For instance, letting $\bar{R}^2$ be the average R^2 of the observed variables, a cutoff of $\text{SRMR} / \bar{R}^2$ perfectly separates between close and non-close fitting models in [Figs. 2 and 3](#), regardless of model size, factor loading, or sample size ([Shi et al., 2018](#)).

Why should we care about model fit? Fit predicts parameter bias

A great deal of research has been devoted to model fit. Yet, very little research has been devoted to the implications of poor model fit, i.e., why model fit matters (but see [Bandalos, 2002](#)). [Steenkamp and Maydeu-Olivares \(2022\)](#) recently showed how the degree of misfit (i.e., goodness of fit indices values) predicts parameter bias, and hence the accuracy of substantive inferences. More specifically, they showed how cross-loadings incorrectly set to zero in confirmatory factor analysis models are expressed through the correlations between the factors, leading to biased factor correlations and to biased structural (regression) parameter estimates. Most importantly, they showed how the magnitude of bias can be predicted from goodness of fit indices. We show population results graphically in [Fig. 4](#) for two goodness of fit indices: the RMSEA (an absolute fit index), and the CFI (a relative fit index). For the RMSEA, we see in [Fig. 4](#) that the number of indicators per factor, the magnitude of the substantive loading, and the RMSEA, along with their interactions predict the natural log of the difference between the true and estimated inter-factor correlation. Across the

Fig. 3 Population and average sample SRMR when fitting a one factor model to two factor model data

Note: rho denotes the correlation between the factors, N is sample size. Data were generated so that all items had a common standardized factor loading (0.30, 0.60, and 0.90), 1000 replications were obtained per condition, pop is the population value -common for (A) and B), and the red solid line corresponds to Hu and Bentler's (1999) cutoff. Models are to be retained if estimated SRMR is below the suggested cutoff.

Fig. 4 Relationship between population model fit and parameter bias in confirmatory factor analysis models when the data generating model involves cross-loadings for 25% of the items and the fitted model has no cross-loadings

Note: The data generating models is a two-factor model. 252 conditions were obtained by crossing true factor correlation (−0.5, −0.3, −0.1, 0.1, 0.3, 0.5), number of indicators per factor (4, 8, 12), magnitude of the substantive factor loadings (0.4, 0.6), and magnitude of the cross-loadings (−0.3, −0.2, −0.1, 0, 0.1, 0.2, 0.3). Error variances were set so that the resulting covariance matrix has a unit diagonal. The fitted model was a two-factor analysis model without cross-loadings. For each index, bias is plotted against the main drivers of the behavior of the index.

panels of Fig. 4A, R^2 ranges between 70% and 88%. For the CFI, we see in Fig. 4 that whether the sign of the cross-loadings agrees with the sign of the interfactor correlation, the absolute value of the interfactor correlation, and the CFI, along with their interactions predict the difference between the true and estimated inter-factor correlation. Across the panels of Fig. 4B, the percentage of variance of parameter bias explained ranges between 81% and 97%

These results provide convincing evidence that the size of model misfit matters.

Model fit with discrete observed data

When the observed variables are discrete (as in responses to test items) and they are modeled as discrete, the observed responses can be gathered in a contingency table with C cells. When all n items consist of the same number of categories, K , $C = K^n$. The two standard goodness of fit statistics for discrete data are Pearson's statistic, $X^2 = N \sum_{c=1}^C (p_c - \hat{\pi}_c)^2 / \hat{\pi}_c$, and the likelihood ratio statistic, $G^2 = 2N \sum_{c=1}^C p_c \ln(p_c / \hat{\pi}_c)$, where $\hat{\pi}_c$ denotes the probability of cell c under the model, and p_c denotes the sample proportion. When maximum likelihood estimation is used, asymptotic p -values for both statistics can be obtained using a chi-square distribution. However, these asymptotic p -values are only correct when all expected frequencies $N\hat{\pi}_c$ are large (>5 is the usual rule of thumb). A practical way to evaluate whether the asymptotic p -values for X^2 and G^2 are valid is to compare them. If the p -values are similar, then both are likely to be correct. If they are very different, it is most likely that both p -values are incorrect. Unfortunately, as the number of cells in the table (i.e., possible response patterns) increases, the expected frequencies must become small (as the sum of all C probabilities must be equal to 1). As a result, when the number of item categories is large (say >4) the asymptotic p -values almost invariably become inaccurate as soon as $n > 5$.

Obtaining accurate p -values by pooling cells a priori

Accurate p -values for test statistics can be obtained by pooling cells of the contingency table so that larger expected frequencies are obtained. Pooling must be performed a priori, before the data is observed, so that the distribution of test statistics can be approximated by a reference distribution. The margins of the contingency table provide a straightforward way to pool cells a priori. We illustrate the relationship between cell probabilities and marginal probabilities using the following 2×3 contingency table:

	$X_2 = 0$	$X_2 = 1$	$X_2 = 2$
$X_1 = 0$	π_{00}	π_{01}	π_{02}
$X_1 = 1$	π_{11}	π_{11}	π_{12}

This table can be characterized using the 6 cell probabilities $\pi = (\pi_{00}, \dots, \pi_{12})'$ that add up to one (so that there are only 5 mathematically independent cell probabilities). Alternatively, this table can be characterized using the 3 univariate probabilities, $\pi_1 = (\pi_1^{(1)}, \pi_2^{(1)}, \pi_2^{(2)})$,

$$\pi_i^{(k)} = \Pr(X_i = k), \quad (8)$$

and 2 bivariate probabilities, $\pi_2 = (\pi_{12}^{(1)}, \pi_{12}^{(2)})$,

$$\pi_{ij}^{(k,l)} = \Pr(X_i = k, X_j = l), \quad (9)$$

Both characterizations (5 cell probabilities, or 5 marginal probabilities) are equivalent: Given $\pi = (\pi_{00}, \dots, \pi_{12})'$ we can determine $\pi = (\pi_1^{(1)}, \pi_2^{(1)}, \pi_2^{(2)}, \pi_{12}^{(1)}, \pi_{12}^{(2)})$, and vice versa. As a result, we can write Pearson's X^2 as a quadratic form of residuals using one characterization or the other (Maydeu-Olivares and Joe, 2005, 2006).

The equivalence extends to contingency tables of any dimension (i.e., regardless of K and n). For instance, the responses to n binary items can be characterized by the $2^n - 1$ cell probabilities or by the $\binom{n}{1} = n$ univariate probabilities $\pi_i^{(k)}$, plus $\binom{n}{2} = n(n-1)/2$ bivariate probabilities $\pi_{ij}^{(k,l)}$, plus $\binom{n}{3}$ trivariate probabilities, ..., up to $\binom{n}{n}$ n -way probabilities, and Pearson's X^2 can be written as a quadratic form in residual proportions up to n -way order.

Since data sparseness leads to a poor approximation of the sampling distribution of test statistics by their reference asymptotic distribution, Maydeu-Olivares and Joe (2005, 2006) proposed for goodness of fit testing to use only residuals in proportions up to the highest level that the model is identified. This amounts to pooling cells a priori so that the resulting statistic can be well approximated by its reference asymptotic distribution in small samples.

Since most models are identified (they can be estimated) using only univariate and bivariate probabilities (as described in the 2×3 table above), they suggested to use only univariate and bivariate residual proportions (the difference between the observed and expected probabilities). This yields their test statistic M_2 which has become the gold standard for goodness of fit testing when the observed variables are discrete. Statistics such as M_2 are referred to as limited information goodness of fit statistics because they disregard information contained in the higher order marginals of the table.

Overall goodness of fit statistics and goodness of fit indices: using univariate and bivariate residuals, item means, cross-products and correlations under the model

M_2 is a member of a larger family of statistics of the form (Joe and Maydeu-Olivares, 2010)

$$M_K = N \hat{\mathbf{e}}_K' \hat{\mathbf{C}}_K \hat{\mathbf{e}}_K, \quad \mathbf{C}_K = \mathbf{\Gamma}_K^{-1} - \mathbf{\Gamma}_K^{-1} \Delta_K (\Delta_K' \mathbf{\Gamma}_K^{-1} \Delta_K)^{-1} \Delta_K' \mathbf{\Gamma}_K^{-1}, \quad (10)$$

In (10), $\hat{\mathbf{e}}_K = \mathbf{k} - \hat{\mathbf{k}}$ denote the residuals: $\mathbf{k}$ denote some sample summary statistics with asymptotic covariance matrix $\mathbf{\Gamma}_K$, $\hat{\mathbf{k}}$ denotes the expected summary statistics (which depend on a smaller set of parameters $\boldsymbol{\theta}$) evaluated at the values of the estimated parameters, and Δ_K denotes the matrix of derivatives of κ with respect to $\boldsymbol{\theta}$. Joe and Maydeu-Olivares (2010) showed that the more highly summarized the data are, the more accurate the empirical Type I errors, and the higher the power of the test.

More specifically, M_2 is of the form (10) where the summary statistics κ contain all the univariate and bivariate probabilities (8) and (9). When all items consist of the same number of categories, K , there are $n(K-1)$ univariate probabilities $\pi_i^{(k)}$, $\frac{n(n-1)}{2}(K-1)^2$ bivariate probabilities $\pi_{ij}^{(k)(l)}$, and M_2 is asymptotically distributed as a chi-square with degrees of freedom equal to $n(K-1) + \frac{n(n-1)}{2}(K-1)^2$ minus the number of estimated parameters.

When n and K are large, very large matrices need to be stored in memory. Also, for large K , bivariate tables may be sparse, leading to slightly inaccurate p -values of M_2 (Cai and Hansen, 2013). When data is ordinal, $K \geq 3$, we can summarize the data further, which would lead to more accurate p -values and higher power. Returning to the 2×3 table of the previous section, if X_2 , which consists of 3 categories, is ordinal, we can compute the item means and cross-products expected under the fitted model as follows

$$\mu_1 = \pi_1^{(1)} \quad \mu_2 = 1\pi_2^{(1)} + 2\pi_2^{(2)} \quad (11)$$

$$\mu_{12} = 1 \times 1 \times \pi_1^{(1)(1)} + 1 \times 2 \times \pi_1^{(1)(2)} \quad (12)$$

Then, a quadratic form (10) can be constructed using the n item means μ_i and $n(n-1)/2$ cross-products μ_{ij} . We refer to this statistic for ordinal data as M_{ord} (Cai and Hansen, 2013; Maydeu-Olivares, 2013). If the data are nominal is not meaningful to compute this statistic (but see Starr et al., 2021). When all items are binary $M_{ord} = M_2$ and no further summarization of the univariate and bivariate tables is obtained.

M_{ord} cannot be used if the number of categories is large and the number of items is small due to lack of degrees of freedom for testing. For instance, for a unidimensional logistic graded-response model (e.g., Samejima, 1969), the number of items must be larger than the number of categories plus two (i.e., $n \geq K + 2$) for the degrees of freedom M_{ord} to be positive. Note that the test statistics (10) are completely general and can be used with any model, for instance with cognitive diagnostic models (Hansen et al., 2016; Liu et al., 2015).

For ordinal data, a statistic that combines features of M_2 and M_{ord} , M_{mixed} may be the best choice (Cai and Monroe, 2014). More specifically, this test uses the $n(K-1)$ univariate residual proportions (8) (as in M_2) and the $n(n-1)/2$ bivariate cross-products (12) (as in M_{ord}).

Note that the limited information test statistics (10) and Browne's test statistic have the same form. This is not accidental, as there is an increasing integration of methods between the categorical and continuous outcomes literatures. For instance, tests of close fit are now routinely employed with discrete data and goodness of fit indices have recently been proposed that mirror those used with continuous outcomes such as RMSEAs (Maydeu-Olivares and Joe, 2014), and TLI (Cai et al., 2021) using M statistics, or the Correlation Root Mean Squared Residual (CRMR: Maydeu-Olivares and Joe, 2014) suitable for binary or ordinal data.

The CRMR can be estimated as

$$\widehat{CRMR} = \sqrt{\sum_{i < j} \frac{(r_{ij} - \hat{\rho}_{ij})^2}{n(n-1)/2}}, \quad (13)$$

where r_{ij} and $\hat{\rho}_{ij}$ denote the sample and expected Pearson correlations. Using (11) and (12), the expected variances, covariances, and expected Pearson correlation among the categorical variables in our example are

$$\sigma_{11} = 1^2 \pi_1^{(1)} - \mu_1^2, \quad \sigma_{22} = 1^2 \pi_2^{(1)} + 2^2 \pi_2^{(2)} - \mu_2^2, \quad (14)$$

$$\sigma_{12} = \mu_{12} - \mu_1 \mu_2, \quad \rho_{12} = \frac{\sigma_{12}}{\sqrt{\sigma_{11} \sigma_{22}}}. \quad (15)$$

Maydeu-Olivares and Joe (2014) reported that the population RMSEA₂ computed using the M_2 statistics depend on the number of categories K and suggested that a cutoff of RMSEA₂ = 0.089, 0.05, and 0.05/($K-1$) indicate adequate, close, and excellent fit, respectively. For the CRMR, they suggested cutoffs of 0.05, 0.027, and 0.027/($K-1$) indicate adequate, close, and excellent fit, respectively.

Piecewise assessment of fit and model modification

One of the main tasks performed in educational research is test construction. As a result, after the parameters have been estimated using all the items, there is particular interest in identifying misfitting items. Pearson's X^2 cannot be applied to assess the fit of single items as there are no degrees of freedom available for testing. X^2 can be applied to pairs of items but it does not follow a chi-square distribution; parameters would need to be estimated using only the items involved in the pair for X^2 to follow a chi-square distribution (Maydeu-Olivares and Liu, 2015). Liu and Maydeu-Olivares (2014) proposed using a mean and variance adjustment to X^2 to overcome this problem. They also compared the performance of a variety of statistics with known asymptotic distribution in identifying misfitting items. They concluded that z statistics for means and bivariate cross products performed best in terms of Type I and II errors. These statistics are

$$z_i = \frac{\bar{x}_i - \hat{\mu}_i}{SE(\bar{x}_i - \hat{\mu}_i)}, \quad z_{ij} = \frac{\bar{x}_{ij} - \hat{\mu}_{ij}}{SE(\bar{x}_{ij} - \hat{\mu}_{ij})}, \quad (16)$$

where $\bar{x}_i$ and $\bar{x}_{ij}$ denotes the sample means and cross products, respectively. Alternatively, a mean and variance corrected X^2 could be used. In closing, as in structural equation modeling, modification indices can also be employed in these models (Glas, 1999; Liu and Thissen, 2012, 2014).

Model selection indices

For some models with discrete or continuous indicators, it may not be possible to assess model-data fit. In those cases, researchers often simply use information criteria indices to select the best fitting model among a set of competing alternatives. The two most popular information criteria GOF indices are Akaike's (1974) information criterion (AIC), and Schwarz (1978) Bayesian information criterion (BIC),

$$AIC = -2L + 2q, \quad BIC = -2L + q \ln(N). \quad (17)$$

where L denotes the loglikelihood of the data, q the number of estimated parameters, and N sample size. We note that the AIC and BIC are not goodness of fit indices, as they do not provide interpretable information about the magnitude of model-data fit. Rather, they are model selection indices. Given a data set, a researcher chooses either the AIC or BIC, and computes it for all models under consideration. Then the model with the lowest index is selected. Notice that both the AIC and BIC combine absolute fit with model parsimony. That is, they penalize adding parameters to the model, but they do so differently. Of the two, the BIC penalizes adding parameters to the model more strongly than the AIC.

Numerical examples

Factor analysis

The most widely used instrument to assess satisfaction with life is the SWLS (Diener et al., 1985). It consists of 5 items which are to be rated on a 7-point scale ranging from 1 (*strongly disagree*) to 7 (*strongly agree*). We used a US nationally representative sample. Sample size is $N = 543$. We treated the data as continuous and fitted a one factor model. In this example, the likelihood ratio test statistic and Browne's test provide nearly identical results and we use the more popular likelihood ratio test, adjusted by its the mean and variance to account for possible non-normality of the data, to assess model-data fit. Fit results are provided in Table 1.

We see in this table that the model does not fit the data exactly: $\bar{T}_{LR} = 24.88$, 5 df, $p < 0.001$. Hu and Bentler (1999) suggested that "for ML estimation, a cutoff value close to 0.95 for TLI and CFI, a cutoff value close to 0.08 for SRMR, and a cutoff value close to 0.06 for RMSEA are needed before we can conclude that there is a relatively good fit between the hypothesized model and the observed data". The results provided in Table 1 suggest that the model provides a relatively good fit according to the CFI, TLI, and SRMR, but not according to the RMSEA. The use of the RMSEA in models with few degrees of freedom is not recommended (Kenny et al., 2015; Shi et al., 2022). With few degrees of freedom, the sampling variability of the RMSEA increases, and sample estimates tend to reject well-fitting models.

Since the model provides a good enough fit using commonly used criteria, we could stop here, but inferences based on this model could be somewhat biased, as the model is rejected. To identify the source of misfit, we used z statistics (1) and modification indices.

The z statistics are presented in Table 3 and enable us to identify parts of the population covariance matrix that are not well reproduced by the fitted one factor model. In this table we also provide residual correlations which may be used to assess the magnitude of the misfit. The only bivariate z statistic that is statistically significant at the 5% level involves items 4 and 5. These two items involve satisfaction with past life, whereas the first three items involve satisfaction with present life. This suggests that an alternative model for these data is a two factor model: satisfaction with present life (measured by items 1 to 3) and satisfaction with past life (measured by items 4 and 5).

Table 1 Modeling satisfaction with life using factor analysis: overall goodness of fit results.

Criterion	Model		
	One factor model	Two factor model	One factor model dropping item 5
χ^2	24.88	0.689	0.489
Df	5	4	5
p	<0.001	0.95	0.78
RMSEA	0.086	0	0
$p(\text{RMSEA} \leq 0.05)$	0.033	0.996	0.935
SRMR	0.040	0.005	0.005
CFI	0.955	1	1
TLI	0.911	1	1
AIC	9959.843	9934.273	7831.607
BIC	10024.300	10003.027	7883.172

Notes: The two factor model involves correlated factors with indicators {1,2,3}, and {4,5}, respectively; χ^2 = mean and variance corrected likelihood ratio statistic, df = degrees of freedom of the null hypothesis that the fitted model reproduces exactly the population means and covariances; p = p -value associated with the null hypothesis of exact fit; RMSEA = Root Mean Squared Error of Approximation; $p(\text{RMSEA} \leq 0.05)$ = p -value associated with a null hypothesis that the population RMSEA is less or equal to 5%; SRMR = Standardized Root Mean Squared Residual; CFI = Comparative Fit Index; TLI = Tucker-Lewis Index; AIC = Akaike's information criterion; BIC = Bayesian information criterion. Results were obtained using Mplus (Muthén and Muthén, 2017). RMSEA, CFI, TLI estimates are not adjusted for non-normality. SRMR denotes the sample (biased) estimate.

On the other hand, the largest modification index obtained when fitting a one factor model involves the covariance between the errors of items 4 and 5, MI = 24.489, leading to an expected correlation of the errors of these items of 0.25. Thus, one could fit a one factor model with a correlation between the errors of these items. In this case, a one factor model with correlated errors and a confirmatory two factor model are equivalent (they yield the same fit) and we selected the two factor model. Goodness of fit results for this model are also provided in Table 2. We see that this model fits extraordinarily well with just one more parameter: $\bar{T}_{LR} = 0.69$, 4 df, $p = .95$. Yet, an alternative model can be obtained by dropping the worst fitting item, which can be computed as the average of the absolute value of the z statistics. This is item 5, and upon removing this item we obtain $\bar{T}_{LR} = 0.49$, 2 df, $p = 0.78$. The goodness of fit indices for this model (see Table 2) are very similar to those of the two factor model. A higher precision of measurement is obtained with the models for 5 items, than with this four item model; therefore, we still choose the two factor model.

We also provide in Table 2 the AIC and BIC for the models considered. These indices suggest choosing the two factor model over the one factor model. We note that the AIC and BIC are considerably lower for the four item model. However, the AIC and BIC should not be used to compare models with a different number of variables.

Item response theory

In the second application, we consider fitting a one-dimensional item response theory (IRT) model to the Positive Problem Orientation (PPO) scale of the Social Problem Inventory-Revised (SPSI-R D'Zurilla et al., 2002). The female Spanish normative data (Maydeu-Olivares et al., 2000) are analyzed. The sample size is 692. The scale consists of five five-category items. A number of IRT models can be fitted to these data, such as Samejima's (1969) graded response model, or Bock's (1972), Thissen et al. (2015) nominal model. There is some evidence (Maydeu-Olivares, 2005) that Samejima's model is the best fitting model in empirical applications involving ordinal data, and it is the model that we fitted. Goodness of fit results are provided in Table 4. There are $5^5 = 3125$ possible response patterns. These data are sparse and Pearson's χ^2 and the likelihood ratio G^2 statistic yield conflicting conclusions, both on 3099 degrees of freedom: χ^2 yields a p -value of 0 and G^2 yields a p -value of 1. Neither p -value is accurate. M_2

Table 2 Modeling satisfaction with life using factor analysis: residual correlations (below the diagonal) and z statistics (above the diagonal).

Item	1	2	3	4	5
1	0	0.378	0.226	-0.204	-0.717
2	0.006	0	1.665	-1.371	-1.717
3	0.003	0.020	0	-1.601	-1.344
4	-0.005	-0.028	-0.024	0	4.249
5	-0.020	-0.039	-0.026	0.166	0

Notes: z statistics larger than 2.93 are statistically significant at the 5% level with a Bonferroni correction.

Table 3 Modeling positive problem orientation using a unidimensional IRT graded model: Overall goodness of fit results.

Statistic	Statistic	df	P
χ^2	66,054.18	3099	0
G^2	1098.26	3099	1
M_2	463.11	155	<0.001
M_{mixed}	8.96	5	0.11
RMSEA ₂	0.054		
RMSEA _{mixed}	0.034		
CRMR	0.030		

Notes: Pearson's χ^2 and the likelihood ratio test statistic G^2 are full information test statistics. M_2 and M_{mixed} are limited information test statistics. M_2 assesses fit to all bivariate tables, M_{mixed} assesses fit to all univariate table and the ordinal cross-products. RMSEA₂ and RMSEA_{mixed} are RMSEAs computed based on M_2 and M_{mixed} , respectively. CRMR = Correlation Root Mean Squared Residual.

Table 4 Modeling positive problem orientation using a unidimensional IRT graded model: univariate and bivariate ordinal z statistics.

Item	1	2	3	4	5	Average
1	-3.31	-3.29	-2.10	-3.83	-2.48	3.00
2	-3.29	1.29	-1.62	-0.10	-2.00	1.66
3	-2.10	-1.62	-2.00	-4.41	-1.76	2.38
4	-3.83	-0.10	-4.41	-2.10	-2.68	2.62
5	-2.48	-2.00	-1.76	-2.68	-1.35	2.06

Notes: Univariate z statistics in the diagonal. We have boldfaced the z statistics significant at an overall 5% level using the Benjamini-Hochberg procedure. The average column is the row average of absolute values of z statistics.

yields 463.11 on 155 degrees of freedom, and the 90% confidence interval for RMSEA₂ is (0.05; 0.06). Since $p(\text{RMSEA}_2 < 0.05) = 0.14$, we conclude that the hypothesized model provides a close fit to the data using the cutoff of [Maydeu-Olivares and Joe \(2014\)](#). The ordinal M statistic cannot be computed for these data due to lack of degrees of freedom for testing. We can compute the M_{mixed} statistic which assesses fit using the univariate margins and the ordinal cross-products. We obtain $M_{\text{mixed}} = 8.96$ on 5 df, $p = 0.11$, so we cannot reject that the model fits exactly using this statistic, but we feel this result needs to be interpreted cautiously in this application, as there are no degrees of freedom to assess the ordinal associations. We also computed the CRMR (13), obtaining 0.030. Hence, on average, the residual Pearson's correlations after fitting the graded model are around this magnitude, which suggests that the degree of misfit of the model is quite small.

To investigate how the fit could be improved, we computed all univariate ordinal z_i statistics and ordinal bivariate z_{ij} statistics (16). They are displayed in [Table 4](#). The statistics that are significant at the 5% level using the Benjamini-Hochberg method are boldfaced. There is only one statistically significant univariate statistic in this table, that of item 1. There are five statistically significant bivariate statistics, three of which involve item 1, and this item shows the largest average z statistic. Item 1, "When my first attempt to solve a problem fails, I believe if I don't give up, I will eventually succeed" is considerably longer than the remaining items in this scale and it includes a conditional clause, which we believe explains why this item fits slightly worse than the rest.

Concluding remarks

A model may fit poorly and yet yield useful predictions. The fact that a model fits poorly simply means that in principle a model could be found to capture more closely the data generating model, whose predictions could be very different. Because inferences are to be as precise and valid as possible, it is important that models reproduce the data generating process as close as possible.

Researchers should always assess the goodness of fit of their models using an overall statistic. If the selected model fits well, researchers should: (a) Assess the power of the statistic against meaningful deviations from the selected model, as it may well be that the statistic has no power to distinguish between the selected model and substantively meaningful alternative models. (b) Perform a piecewise assessment of the selected model to examine if some parts of the data are not well captured by the model. On the other hand, if the model does not fit well, researchers should: (a) Perform a piecewise assessment of the model attempting to determine the source of the misfit. (b) Assess the magnitude of the discrepancy between the fitted model and the data generating model to gauge the extent to which substantive inferences drawn on the fitted model may be biased.

In closing, we encourage researchers to use goodness of fit statistics and indices for which a trustworthy confidence interval (or *p*-value) can be obtained, as doing so captures the effect of sample size. When the observed variables are discrete, this leads to additional computing time, but it protects researchers from discarding items or tests based on faulty statistics.

Introduction

Consider a large-scale test consisting of I items being administered to a group of N students. The test's main goal is typically to estimate each student's proficiency level on the course content under evaluation. A suitable statistical model must be considered to analyze such data. One popular statistical framework commonly used is Item Response Theory (IRT; e.g., Embretson and Reise, 2000; van der Linden, 2018). As it is always the case with statistical modeling, the question of model (mis)fit is of crucial interest. The most common IRT model fit strategy consists of focusing on the item level to determine whether there are large discrepancies between the observed and expected item scores. However, it is arguably the case that the test manager is more interested in collecting model fit information from the student's perspective. In other words, one is interested in assessing whether the response pattern provided by each student is in accordance with the statistical model being used. The question is therefore one of the validity of each student's response pattern, in light of the statistical model at hand. Lack of validity of a student's response pattern will cast doubt on his or her test result. Worse, depending on the proportion of misfitting response patterns in the data set, potentially more test results may be invalid (St-Onge et al., 2011). This is a real concern that should not be ignored (Walker, 2017).

Researchers have spent time studying how to detect misfitting response patterns, in what is nowadays best known as appropriateness measurement or person-fit analysis (PFA). In what follows, we first briefly introduce the main ideas behind IRT. Next, we explain what misfitting response patterns consist of, and what statistical techniques currently exist to aid their detection. Finally, we mention some recent applications of PFA and discuss important aspects to take into account when applying PFA.

Item response theory

IRT models are a mathematical means of relating a person's proficiency to an item's particular characteristics. Fig. 1 display the curves of three such models; these are known as item characteristic functions (IRFs). These simpler models assume that a single latent person trait accounts for the effect on the item score. The more general of the three models is the three-parameter logistic model (3PLM; Bimbaum, 1968), given by

$$P(X_i = 1 | \theta_n) = c_i + (1 - c_i) \frac{1}{\exp[-a_i(\theta_n - b_i)]} \quad (1)$$

In Eq. (1), a_i , b_i , and c_i denote respectively the discrimination, difficulty, and pseudo-guessing parameters of item i ($i = 1, \dots, I$), θ_n is the trait level of person n ($n = 1, \dots, N$), and X_i is the dichotomous score of item i (correct = 1; incorrect = 0). The two-parameter logistic model (2PLM) is a particular case of the 3PLM when $c_i = 0$. The one-parameter logistic model (1PLM), also known as the Rasch model (Rasch, 1960), further constraints the 2PLM by setting the discrimination constant (typically to 1).

There is a large plethora of IRT models beyond those mentioned above, including models that accommodate polytomous item scores, non-parametric models, multidimensional models, models for response times, and models for nonmonotone items (Embretson and Reise, 2000; Sijsma and Molenaar, 2002). Here we focus on unidimensional dichotomous IRT models.

There are various algorithms available for parameter estimation, comparing models, and assessing the fit of an IRT model. Below we focus on one particular model fit strategy.

Fig. 1 Three IRFs. Item parameters: $b = 1$ (1PLM); $a = 2, b = 1$ (2PLM); $a = 1.5, b = 0, c = 0.2$ (3PLM). θ stands for the person's trait parameter.

Person-fit analysis

From a model fit perspective, PFA aims at determining whether person response patterns are as expected based on the model. For example, consider the following response patterns, with scores to ten items in increasing order of item difficulty:

Person A: 1101110100.

Person B: 0100011011.

Person A's response pattern is not very strange and could pertain to an average trait person: Most easy items were correctly answered whereas most difficult items were incorrectly answered. Person B, on the other hand, displays a suspicious set of answers: Most of the correct answers concern the most difficult items in the test. Such response behavior can be the result of one or more idiosyncratic response behavior: Warm-up issues, unfortunate lack of familiarity with the content covered by the easier items, cheating, or something else. Whatever the reason, this response pattern warrants the analyst to exert caution when analyzing and reporting the test results.

PFA allows conducting a systematic analysis of all individual response patterns in a data set. There is a large variety of statistical strategies that can be used in person-fit analysis (e.g., Karabatsos, 2003; Meijer and Sijtsma, 2001; Tendeiro et al., 2016). We will focus on some of the most popular statistics currently in use.

The l_z statistic family

Dragow et al. (1985) introduced the most popular person-fit statistic for dichotomous data in use. The l_z is the standardized log-likelihood of a person's response pattern:

$$l_z = \frac{l_0 - E(l_0)}{\sqrt{V(l_0)}} \quad (2)$$

where $l_0 = \sum_{i=1}^I X_i \ln[P_i(\theta_n)] + (1 - X_i) \ln[1 - P_i(\theta_n)]$, and $E(l_0)$ and $V(l_0)$ are the mean and variance of l_0 , respectively:

$$E(l_0) = \sum_{i=1}^I P_i(\theta_n) \ln[P_i(\theta_n)] + [1 - P_i(\theta_n)] \ln[1 - P_i(\theta_n)]$$

$$V(l_0) = \sum_{i=1}^I P_i(\theta_n) [1 - P_i(\theta_n)] \left[\ln \left(\frac{P_i(\theta_n)}{1 - P_i(\theta_n)} \right) \right]^2.$$

The l_z statistic is asymptotically standard normally distributed under the assumption of no aberrant response behavior, provided the true ability parameters θ_n ($n = 1, \dots, N$) are used. Low scores of l_z (e.g., $l_z < -2$) are indicative of misfit.

One problem with l_z is that practitioners never know the true ability values. These must be estimated and plugged in Eq.(2) in order to compute the statistic. Replacing true with estimated person parameters alters the reference distribution, and that affects computing the statistic threshold needed to determine whether a response pattern should be flagged as aberrant or not. Snijders (2001) developed an improvement now known as the l_z^* statistic which fixes the problem (see also Magis et al., 2012 for an accessible read). Sinharay (2016) further extended Snijders' statistic to mixed format tests (i.e., including both dichotomous and polyt-omous items), and Albers et al. (2016) developed a related statistic suitable for a multiple subtests setting.

Guttman errors

Guttman (1950) proposed a statistic that counts the number of “illogical” pairs of scores within a response pattern. This can easily be understood by considering again the response patterns from persons A and B above. Recall that the scores are ordered in increasing item difficulty. Consequently, one considers an error whenever a 0 precedes a 1, that is, whenever the person answered an easier item incorrectly but a harder item correctly. Such a pair of item scores is known as a Guttman error. Counting all the 01 pairs for each person, we conclude that Person A has $G = 5$ Guttman errors whereas Person B has $G = 19$ Guttman errors. Thus, we tentatively conclude that Person B displays a stranger response pattern than Person A.

However, as can be readily seen, the number of Guttman errors depends on the total number of items for a given sum score. In particular, for a sum S , G has a conditional maximum equal to $S(I-S)$. This property makes the comparison of G between subjects with different sum scores impractical. Luckily, we can norm G by dividing it by this conditional maximum, leading to a statistic known as “ G normed” (Tendeiro et al., 2016), which does allow comparisons between subjects with different sum scores. Extensions of both G and its normed version to polytomous data were developed by Molenaar (1991) and Emons (2008), respectively.

The extended caution indices family

Sato (1975) proposed the caution index (see also Harnisch and Linn, 1981). In what follows, consider that the items are ordered in increasing order of difficulty. The caution index is given by

$$C_n = 1 - \frac{\text{Cov}(\mathbf{x}_n, \mathbf{i})}{\text{Cov}(\mathbf{x}_n^*, \mathbf{i})} \quad (3)$$

where $\mathbf{x}_n$ is the response pattern of respondent n , $\mathbf{x}_n^*$ is the associated Guttman vector, and $\mathbf{i}$ is the vector with item proportions of correct answers, across examinees. To understand what the Guttman vector is, consider the response pattern of Person B introduced before: $\mathbf{x}_n = 0100011011$. Recall that the item scores are ordered in increasing item difficulty. For this response pattern the sum-score equals 5, which implies a perfect Guttman response pattern $\mathbf{x}_n^* = 1111100000$. Thus, ideally, the 5 correct items should be the 5 easier items. C_n is zero for Guttman vectors and its value tends to increase for misfitting response patterns, hence cautioning the researcher about interpreting such item scores.

Tatsuoka and Tatsuoka (1982) and Tatsuoka (1984) generalized the caution index in what is now known as the extended caution indices (ECIs). There are six such ECIs, all of which consist of variations to Sato’s caution indexed shown above (see Meijer and Sijtsma, 2001, Eqs. 42–47). Also some standardized versions of these coefficients are available (Tatsuoka, 1984). Sinharay (2016) offered asymptotic corrections to the standardized versions of the ECIs, following a similar procedure developed by Snijders (2001) for the I_z .

Person response function

Fig. 1 previously displayed examples of IRFs. A similar plot can be conceived such that the person and item swap roles; the result is the person response function (PRF; Lumsden, 1978; Weiss, 1973). One example is shown in Fig. 2. Thus, for a fixed person, one can conceive of a functional relation between a continuous item difficulty parameter and the probability of answering an item of that difficulty correctly. This function in theory is non-increasing. Thus, observed deviations from this pattern may give away deficiencies in a person’s response pattern. For example, an observed increasing PRF should warrant concern. This idea was first explored by Trabin and Weiss (1983), and later expanded by Klauer and Rettig (1990), Nering and Meijer (1998), Sijtsma and Meijer (2001), and Walker et al. (2018).

Fig. 2 Example of a PRF. δ stands for a generic item difficulty parameter.

Computerized adaptive testing

One important form of assessment is the computerized adaptive test (CAT). A CAT is a dynamic assessment which unfolds as the person takes the test. For a given test taker, each item is selected depending on his or her test performance up to that moment. In this way, different items may be assigned to different persons. Because items are optimally selected based on the up-to-date information for a given person, CATs have the potential of being shorter and of assessing each person more efficiently than traditional tests.

Some person-fit strategies adapted to CATs have been developed (Armstrong and Shi, 2009; Tendeiro et al., 2013; van Krimpen-Stoop and Meijer, 2001). These techniques are based on the theory of statistical process control (Page, 1954). In particular, cumulative sum control charts have been used in PFA. These charts are sensitive to sequential types of aberrant responding, both locally and globally. A response pattern is flagged once the chart line surpasses either an upper or lower control limit.

Comparative performance of person-fit statistics

Because the offer is so wide, practitioners may feel at a loss when they decide to choose one person-fit approach. Many simulation studies have compared the performance of various person-fit statistics; some examples include Karabatsos (2003) and references therein, Tendeiro and Meijer (2014), Ferrando (2015), and Sinharay (2017). Performance is typically judged by considering the power and false positive rates under varying item, test, and person characteristics (e.g., dichotomous vs. polytomous items, test length, aberrant response behavior). The conclusion is that there is no overall winner across the board, as results differ according to the many testing covariates. Practitioners instead tend to resort to popularity, and that also helps explaining why for example the l_z statistic and its derivatives have met a great deal of endorsement.

Applications

Recent years have witnessed an increase of interest of person-fit analysis in various fields, educational and otherwise. For example, de Vroege et al. (2018) used PF analysis to detect aberrant response patterns before fitting an exploratory factor analysis to data from a clinical study of alexithymia (a personality trait). Wanders et al. (2015) used PF to identify atypical profiles of depressive symptoms. Conrad et al. (2010) used PF to screen for suicide risk among people undergoing alcohol and drug treatment. PF is also useful to detect careless responding, for instance in internet-based quality of life assessments (Felt et al., 2017; Schneider et al., 2018). PF has also been applied to detect test collusion in large-scale testing (Belov, 2013). Cui and Li (2015) applied PF in the framework of cognitive diagnostic assessment. Response time analysis has also received attention, as response times for aberrant responders tend to be differently distributed (e.g., Lee and Chen, 2011). Finally, we can mention the work of Egberink et al. (2010) as one empirical application of CUSUM PFA.

Aspects to consider

In setting up a person-fit analytical strategy, several aspects must be considered. For example, how to choose a threshold value is important for decision making. The value -1.96 is commonly used for l_z^* , so persons with scores below this threshold are flagged as potentially aberrant. However, the specification of the threshold is far from obvious, especially when the person-fit statistic's sampling distribution is unknown. Mousavi et al. (2019) have recently explored and compared various strategies for determining suitable threshold values.

Another important consideration is IRT model misspecification. Poor fit of an IRT model may have detrimental consequences at various levels (Crişan et al., 2017), including PF analyses (Hong et al., 2020). It is therefore important to evaluate the quality of model fit before capitalizing on the results of a PFA.

Implementing PFA may be difficult for practitioners with limited programming expertise. Luckily, the R package PerFit (Tendeiro et al., 2016; see also Meijer et al., 2016) offers an accessible implementation of the most popular person-fit statistics currently in use.

Summary

Ascertaining whether response patterns are valid is a basic requirement in test scoring. PFA offers a useful set of tools that can assist practitioners. We offered a broad overview over PFA, highlighting both its features and potential. Research in PFA is still ongoing and further developments can be expected in the near future. It is our hope that PFA is more consistently used, thus increasing the robustness and fairness of test results.

Glossary

Posterior predictive distribution Posterior predictive distribution is a distribution of future observable data conditional on observed data

Posterior predictive p -value Posterior predictive p -value is the probability that the replicated data could be more extreme than the observed data as measured by the discrepancy measure

Posterior predictive model checking Posterior predictive model checking is a methodology used for assessing Bayesian model fit using replicated data simulated from the posterior predictive distribution

Relative model-data fit Critical evaluation and comparison of two or more models under consideration for the purpose selecting a model based on the balance between best fit and predictive accuracy

Multilevel model Also known as hierarchical models, random-effects models, and mixed-effects models. Models in which parameters are considered random variables with some specified distribution at one or more levels and are fixed at other levels

Introduction

The goal of statistical modeling, whether Bayesian or frequentist, is for researchers and practitioners to construct a model or series of models to help describe and make inferences about complex processes. Before the researcher can make inferences from any model, the model must be evaluated for its adequacy, regardless of estimation framework. This process of model evaluation is often referred to as model-data fit or model checking. It is the intended inferences and interpretation of model results that drive model checking procedures, with the researcher determining if the inferences made from the results are reasonable. Researchers seek to learn, through model checking procedures, specifics of the model's limitations and failures. For example, one model may provide appropriate inferences for individuals at the lower end of an observed score distribution, but inappropriate conclusions for individuals at the upper end of the distribution.

Gelman et al. (1996) provide three approaches of evaluating a model's appropriateness for the data and desired inferences for Bayesian methods. These approaches are: (1) examining the sensitivity of inferences to reasonable changes in the prior distribution and the likelihood; (2) checking that the posterior inferences are reasonable, given the substantive context of the model; and (3) checking that the model fits the data, which is the focus of this entry. Bayesian model checking encompasses both absolute and relative evaluation of model-data fit, mirroring the purposes of model checking in the frequentist framework. Absolute checking of model-data fit involves checking the appropriateness of the model for the observed data to model assumptions and desired inferences. Continuing the observed score example, absolute fit would evaluate, for example, one model fit to the observed score distribution. Relative checking of model-data fit is the process of evaluating one model against other, competing models. Relative fit might compare two competing models to each other (e.g., one symmetric and one allowing for skew), considering both parsimony and inferential errors of the models for the empirical data.

Models estimated in a Bayesian framework rely on posterior predictive model checking (PPMC) for evaluation of absolute fit. While the specifics differ for each class of model (e.g., item response theory, confirmatory factor models), the general PPMC procedure remains consistent. Details of PPMC are provided in the next section of this entry. Relative fit encompasses a broad set of procedures, including Bayes Factors and information criteria. In the final section of the entry, details of model comparison procedures are presented.

Regardless of the type fit evaluation, absolute or relative, Bayesian data analysis proceeds according to five general steps: (1) identify and collect data required to answer the research question, (2) choose a statistical model for the relevant data, (3) specify a prior distribution on the parameters, (4) obtain the posterior distributions for the model parameters (e.g., through Markov chain Monte Carlo [MCMC] estimation), and (5) evaluate model adequacy (Kruschke, 2014). Steps (2) through (5) may repeat until model adequacy is obtained. To ensure that credible model parameters are obtained in the fourth step, it is crucial to ensure convergence of the parameter(s) (Patz and Junker, 1999). For example, the Geweke statistic (Geweke, 1992), Raftery-Lewis diagnostic (Raftery and Lewis, 1992), potential scale reduction factor (PSRF) statistic (Gelman and Rubin, 1992), and a generalization of the PSRF (Brooks and Gelman, 1998) are all popular measures available to evaluate convergence in Bayesian statistics. It is after the convergence checking step that the researcher can begin to evaluate model-data fit.

Absolute fit: posterior predictive model checking

Posterior predictive model checking is a popular Bayesian approach for assessing fit; it was developed out of the posterior predictive methodology (Rubin, 1984). PPMC is based on the simple, intuitive principle that the data generated from the posterior distribution should resemble the observed data if the model provides adequate fit for the data. The posterior predictive distribution (PPD) for replicated data is a distribution of future observable data conditioned on the observed values (Rubin, 1984). That is, PPD is the distribution of simulated, or “replicated,” data that would arise from the model and parameters estimated from observed data. Specifically, the PPD is defined via:

$$p(x_{\text{new}}|\mathbf{x}) = \int p(x_{\text{new}}|\boldsymbol{\theta})p(\boldsymbol{\theta}|\mathbf{x})d\boldsymbol{\theta}$$

where $\boldsymbol{\theta}$ is used as generic notation for all of the model parameters, x_{new} is the replicated data, and $\mathbf{x}$ is the observed data. In practice, the PPD is computed via simulation (Stern and Cressie, 2000). Computing the replicated samples is accomplished by randomly drawing values of the parameter(s) from the posterior distribution, which are then used to simulate the data using the model of interest. This process is repeated many times – often 1000 or more. The end result is a large number of data sets, each the same number of observations as the observed data.

In a simple example, assume a researcher is using a normal distribution to model an outcome variable, X , for n individuals. The model parameters are the mean, μ , and the standard deviation, σ . Although a simple problem such as this may be solved analytically via use of conjugate priors, this and future examples assume the use of MCMC estimation algorithms. In the first replicated data set ($\text{rep} = 1$), parameter values are randomly drawn from the joint posterior distribution (i.e., $\mu_{\text{rep}}, \sigma_{\text{rep}}$) and a data set of sample size n is simulated from a $\text{Normal}(\mu_{\text{rep}}, \sigma_{\text{rep}})$ distribution. In the second replicated data set ($\text{rep} = 2$), a new set of values are randomly drawn from the joint posterior distribution and a new data set of sample size n is simulated from a distribution. This process continues until a large number of data sets are replicated, resulting in the PPD, which can then be compared to the observed data. Specifically, PPMC methods assess which aspects of the data, if any, are or are not captured by the model. Any systematic differences between the observed data set and those of the replicated data sets indicate a failure of the model to explain those aspects of the data (Sinharay et al., 2006).

Systematic differences can be seen graphically, by comparing plots of observed and replicated data, or numerically, through comparison of statistical features of the observed data to the same statistical features of the replicated data. Graphical approaches include commonly used graphs such as the histogram, boxplot, and scatterplot. Numerical approaches make use of discrepancy measures, which are statistical features computed for the observed data and for each of the replicated data sets. Continuing the simple normal distribution example, skewness could be used as the discrepancy measure. Because the model is a normal distribution, which is symmetric with an excess skew of zero, the PPD will reflect this symmetry and lack of skewness. If the observed data does not have significant skewness, then the skewness value from the observed data will be close to the skewness values from the replicated data. But if the observed data does have significant skewness, either positive or negative, then the skewness value from the observed data will not be similar to the skewness values from the PPD. In this way, the specific discrepancy measure can diagnose important aspects of model-data misfit.

Educational measurement example

To demonstrate the utility of the PPMC in educational measurement, PPMC procedures are applied to the Law School Admission Test Section 6 (LSAT6; Bock and Lieberman, 1970). The LSAT6 data has been extensively used in IRT (see Bock and Lieberman, 1970; Thissen, 1982; McDonald, 2013; Kim, 2001) and is publicly available. The data set contains dichotomously-scored item responses from 1000 examinees to 5 items. Fig. 1 presents the distribution of the number of examinees across the total scores obtained on the LSAT6.

Fig. 1 Distribution of the number of examinees obtaining each score on the LSAT6.

The LSAT6 has shown adequate fit to the one-parameter logistic model (1PL; Rasch, 1960). The 1PL IRT model is the simplest IRT model for items that are scored dichotomously and models the probability of a correct response for person i to item j . The mathematical representation is given by:

$$P_{ij}(U_{ij} = 1 | b_j, \theta_i) = \frac{1}{1 + e^{-(\theta_i - b_j)}} \quad (1)$$

where θ_i is the latent ability of examinee i , b_j is difficulty parameter of item j , and $P_{ij}(U_{ij} = 1 | b_j, \theta_i)$ is the probability of a correct response by examinee i on item j given the examinee's latent ability, θ_i , and item difficulty, b_j . The 1PL model is based on a restrictive hypothesis that all items have equal discriminating power and no guessing was present. For the purpose of this illustration, we will demonstrate absolute model-data fit using the 1PL and the two-parameter logistic (2PL; Birnbaum, 1957) models. The 2PL model relaxes one of the restrictive assumptions of the 1PL model by allowing items to vary in discrimination. The 2PL model is given as:

$$P_{ij}(U_{ij} = 1 | a_j, b_j, \theta_i) = \frac{1}{1 + e^{-a_j(\theta_i - b_j)}} \quad (2)$$

where $P_{ij}(U_{ij} = 1 | a_j, b_j, \theta_i)$ represents the probability of a correct response by examinee i on item j given the examinee's latent ability, θ_i , the item difficulty, b_j , and discrimination, a_j , parameters. The Bayesian formulation of the IRT model requires the specification of priors on the item and person parameters. The prior distributions specified in fitting these models are, in this example:

$$a_j \sim \text{lognormal}(0, 4)$$

$$b_j \sim \text{normal}(0, 25)$$

$$\theta_i \sim \text{normal}(0, 1)$$

After fitting the model, we generated replicated data for the PPD. **Fig. 2** displays the distribution of the total scores for the replicated data simulated under the 1PL (top panel) and 2PL (bottom panel) models for a single replicated data set. The two distributions in **Fig. 2** closely resemble the distribution of the observed data shown in **Fig. 1**, indicating that the 1PL and 2PL models both provide reasonable approximations of the observed total score distribution.

This example illustrated one aspect of model-data fit, but it does not illustrate how well other key aspects of the observed data are represented by the models. That is, the resemblance of the distributions in **Fig. 2** shows that graphical checks of the total score distribution alone may not be conclusive. Moreover, interpretation of graphical checks may be subjective. For instance, the PPD may approximate the observed data with respect to total score distribution, but fail to describe other aspects of the posited model, such as the appropriateness of the assumption that all items have the same discriminating power.

Fig. 2 The top panel shows the distribution the total score of the replicated data for the Bayesian 1PL IRT model. The bottom panel shows the distribution of the total score of the replicated data for the Bayesian 2PL IRT model.

Discrepancy measures for PPMC

Meng (1994) and Gelman et al. (1996) have further extended the methodology proposed by Rubin (1984) to quantify discrepancies between the posited model and observed data. Numerical quantification is accomplished by using discrepancy measures and posterior predictive p -values. Given there is no true perfect model, it is important to assess how the model fits the features and inferences of importance to the researcher. These specific aspects of the data can be assessed with the aid of discrepancy measures. Discrepancy measures are chosen to allow researchers to evaluate compatibility of the model with the observed data (Bayarri and Berger, 2000). In principle, any basic descriptive quantities (e.g., mean, minimum, maximum, standard deviation) or inferential statistics (e.g., correlation coefficient, fit indices) can serve as discrepancy measures. Define $T(D)$ to be a discrepancy measure of the observed values, also called the *test statistic*, and $T(D_{\text{rep}})$ is the test statistic for each replicated data set. There is an

Fig. 3 Fit of the replicated 1PL and 2PL data sets to the item-total correlation.

entire distribution of discrepancy measures for the replicated data because there are multiple replicated data sets. Any significant deviation between these discrepancy measures, $T(D)$ and $T(D_{rep})$, is an indication of model misfit.

Zhu and Stone (2012) caution that discrepancy measures should be chosen to reflect sources of potential misfit relevant to a testing application. In essence, the choice of the discrepancy measure is crucial to accurately detect misfit in the model, which could lead to questionable inferences. For example, Sinharay et al. (2006) noted that the correlation of examinee scores with their binary outcomes for a particular item is effective in assessing misfit of a 1PL model associated with the assumption of equal discriminating power across all items. This correlation is the item-total score correlation, which is related to the discrimination, or slope, parameter. If the true model is the 2PL, with varied discrimination parameters, then PPD data generated from the 1PL analysis model, with a single discrimination parameter, may not have similar item-total score correlations.

Continuing the LSAT example, the item-total score correlation was computed for the observed data and for each of the 1000 data sets in the PPD. Fig. 3 illustrates the observed and median item-total correlations across 1000 data sets replicated from the 1PL and 2PL models. The item-total correlations for the 1PL replicated data closely resembles item-total correlations computed from the observed data for all five items. Thus, the 1PL appears to provide an adequate fit of the model to the data for this feature of the data. In contrast, the 2PL appears to underestimate the item-total correlation for items 2 through 5, as indicated by the 50th percentile of the item-total correlation discrepancy measure falling below the observed discrepancy measure's value for those items.

Posterior predictive p -value

In the frequentist framework, a p -value is defined as the probability of observing the test statistic, or one more extreme, under a true null hypothesis (H_0). In the Bayesian framework, the posterior predictive p -value serves as a measure of deviance between the model and the data (Berkhof et al., 2000). The Bayesian posterior predictive p -value is defined as the probability that the replicated data is more extreme than the observed data as measured by the discrepancy measure (Gelman et al., 2013). This probability is given by:

$$p_B = \Pr\{T(D_{rep}) \geq T(D) | x, H_0\} \quad (3)$$

Posterior predictive p -values near 0.5 indicate adequate model-data fit, whereas, values greater than 0.95 or less than 0.05 are often used to indicate poor model-data fit (Sinharay, 2006). The posterior predictive p -value is computed as follows:

1. Compute the discrepancy measure, $T(D)$, from the observed data set
2. Simulate many posterior predictive data sets (typically 1000 data sets)
3. Calculate $T(D_{rep})$ for each posterior predictive data set
4. Count the proportion of replications for which $T(D_{rep})$ exceeds $T(D)$.

We computed the posterior predictive p -value of the item-total score correlations as the discrepancy measure, for the 1000 replicated data sets. Fig. 4 presents a histogram of the discrepancy measure $T(D_{rep})$, when the 1PL model is used, based on 1000 replications

Fig. 4 Histogram of 1000 1PL model replications for the item-total discrepancy measure, $T(D_{rep})$, for item 2. The vertical line represents the observed discrepancy measure, $T(D)$.

for item 2. The vertical line in the plot indicates the observed discrepancy measure, $T(D)$. Of the 1000 $T(D_{rep})$ values, 503 values were greater than $T(D) = 0.566$, resulting in a posterior predictive p -value of $503/1000 = 0.503$. This posterior predictive p -value suggests the 1PL model is a good fit for item 2 in terms of discrimination, according to the item-total correlation discrepancy measure.

Relative fit

In contrast to evaluation of absolute model-data fit, when evaluating relative model-data fit, a researcher is not generally concerned with checking a particular model, but rather comparison among models with the goal of improving upon and finding or selecting the most useful model. Although the previously discussed PPMC framework is generally referenced when evaluating absolute fit, it may also be used for evaluation of relative model-data fit when particular characteristics of model-data fit are of interest. For example, the item-total score correlation discrepancy measure example illustrated in [Discrepancy measures for PPMC](#) provided evidence of superior fit of the 1PL model relative to the 2PL model. [Li et al. \(2006\)](#) successfully used odds ratios among item pairs as a discrepancy measure to assess the fit of an array of potential IRT testlet models fit to testlet data violating the assumption of conditional independence. Nonetheless, PPMC is generally thought of as a method of assessing absolute fit and is considered concurrently with assessment of relative fit.

Bayes Factors

Given the attention to the frequentist perspective of hypothesis testing, education practitioners and researchers often focus on research designs and analyses centered around null hypothesis significance testing (NHST). For example, pedagogical researchers might question if addition of an inquiry-based-learning component results in higher scientific literacy than simply an experiential learning approach. Such a research question, with competing theoretical models, is framed in such a way that it lends itself to the traditional method of NHST. The model comparison method of Bayes factors is the standard Bayesian hypothesis testing alternative to NHST ([Lewis and Raftery, 1997](#)). In contrast to interpretation of NHST p -values, as illustrated above, Bayes factors quantify the evidence of one hypothesis compared to another on a continuous scale ([Jeffreys, 1961](#)). More specifically, Bayes factors provide a formal method of evaluating the relative probabilities of competing models, translated to hypotheses, given the data. Thus, Bayesian hypothesis testing allows researchers to assess the strength of evidence in favor of one hypothesis over another rather than the NHST practice of simply rejecting, or failing to reject, a null hypothesis.

Consider two competing theoretical models represented by hypotheses H_0 and H_1 . The hypotheses could represent null and alternative hypotheses, regression models with different subsets of predictors, or nested 1PL and 2PL IRT models. The researcher assigns prior probabilities to each hypothesis such that their sum equals 1, $p(H_0) + p(H_1) = 1$. The data x are theorized to come

from H_0 or H_1 , where the sum of the posterior probabilities of each hypothesis equals 1, $p(H_0|x) + p(H_1|x) = 1$. Weighing the relative evidence of H_0 is facilitated by expressing the probabilities of each hypothesis in terms of their odds. Bayes theorem thus gives:

$$\frac{p(H_0|x)}{p(H_1|x)} = \frac{p(x|H_0)}{p(x|H_1)} \times \frac{p(H_0)}{p(H_1)} \quad (4)$$

where the term on the left is the posterior odds of H_0 , the first term on the right is the Bayes factor, which has the form of a likelihood ratio, and the second term on the right is the prior odds of H_0 . Thus, the Bayes factor, denoted as BF_{01} , is the ratio of the marginal densities of the data given the hypotheses (e.g., $p(x|H_0)$). The marginal densities are obtained by integrating out the model parameters θ_j ($j \in \{0, 1, \dots\}$). Note, θ_j may represent a single model parameter or vector of model parameters for model j . The marginal density for hypothesis 0, for example, is obtained by:

$$p(x|H_0) = \int p(x|H_0, \theta_0) p(\theta_0|H_0) d\theta_0 \quad (5)$$

where $p(x|H_0, \theta_0)$ is the likelihood and $p(\theta_0|H_0)$ is the prior for the parameters. Rearranging terms of Eq. (4), we can see the Bayes factor is a ratio of the posterior odds of H_0 to its prior odds:

$$BF_{01} = \frac{p(x|H_0)}{p(x|H_1)} = \frac{p(H_0|x)}{p(H_1|x)} \frac{p(H_0)}{p(H_1)} \quad (6)$$

Accordingly, BF_{01} can be interpreted as the strength of evidence in favor of H_0 or against H_1 . Consider the pedagogical researchers' hypothetical results in Table 1.

Assuming the prior probabilities of both hypotheses are equal ($p(H_0) = p(H_1) = 0.50$), the obtained $BF_{01} = \frac{p(x|H_0)}{p(x|H_1)} = \frac{.56}{.44} = 1.27$ indicates that after conducting the experiment, H_0 is 1.27 times more likely than H_1 . Kass and Raftery (1995, p. 777) provided guidelines for interpreting the strength of H_0 relative to H_1 in terms of the raw metric of BF_{01} and in the metric of twice the natural log of BF_{01} (see Table 2). Note that in practice it is more common to express Bayes factors in terms of twice their natural log:

$$2 \log BF_{01} = 2 \log \frac{p(x|H_0)}{p(x|H_1)} = 2 [\log p(x|H_0) - \log p(x|H_1)] \quad (7)$$

In practice, calculations of exact marginal densities, and therefore exact Bayes factors, are computationally difficult for more complex models (e.g., when non-conjugate priors are used). Accordingly, several approximations have been developed to facilitate use of Bayes factors (for different approximations, see Bollen et al., 2012; Han and Carlin, 2001; Kass and Raftery, 1995; Newton and Raftery, 1994; Sinharay, 2001). For example, Entink et al. (2009) demonstrate the use of Newton and Raftery's (1994) importance sampling method for comparing nested multilevel IRT models. One of the most common approximations, however, is Schwarz's (1978) Bayesian information criterion (BIC; Bollen et al., 2012).

Information criterion

Bayesian information criterion

BIC is an information criteria-based relative-fit index that was developed as an approximation of marginal densities (e.g., $p(x|H_1)$) to simplify computation of Bayes factors (Kass and Raftery, 1995; Gelman et al., 2013). As with other information criteria-based indices, the simplicity of BIC lies in the two basic components required for its computation: deviance and a penalty term. In general,

Table 1

	Hypothesis	Probability
Inquiry-based-learning component	$H_{10}H_1$	0.56
Experiential learning approach only	$H_{21}H_2$	0.44

Table 2

Guidelines for Interpreting Bayes Factors		
Evidence against H_{21}	$BF_{1201}BF_{12}$	$2\log BF_{1201}$
Not worth more than a bare mention	1–3	0–2
Positive	3–20	2–6
Strong	20–150	6–10
Very strong	> 150	> 10

Source: Kass and Raftery (1995, p. 777).

the deviance is equal to minus 2 times the log-likelihood given a point estimate, $-2 \log p(x|\hat{\theta})$. The penalty term represents the effective number of parameters in the model and is a measure of model complexity. With respect to BIC, the maximum likelihood estimate, $\hat{\theta}_{MLE}$, is used as the point estimate and the penalty term consists of the product of the number of free parameters, k , and the natural log of the sample size, N . The formula for BIC is thus:

$$BIC = -2 \log p(x|\hat{\theta}_{MLE}) + k \log N \quad (8)$$

When used for relative model comparison, models with smaller values of BIC are preferable. Notice as sample size increases, BIC provides an increasingly larger penalty per parameter and thus tends to select more parsimonious models. In fact, BIC tends to overly penalize complex models (Bollen et al., 2012).

To approximate Bayes factors, Raftery (1995) showed that BIC values for each model can be substituted for the respective marginal densities as follows:

$$2 \log BF_{01} = 2 \log \frac{p(x|H_0)}{p(x|H_1)} \approx \frac{BIC_0}{BIC_1} = BIC_0 - BIC_1 \quad (9)$$

The difference between BIC values can then be evaluated using the guidelines in Table 2. Note, the original Bayes factor metric can be obtained via $BF_{01} \approx \exp\left(\frac{1}{2}BIC_0 - BIC_1\right)$. A common criticism of Bayes factors is their sensitivity to the prior distributions used on the parameters (Kass and Raftery, 1995). Accordingly, Bayes factors should be interpreted with caution, and prior sensitivity analyses should be performed when possible. Graphical prior sensitivity analyses have been shown to be useful approaches for visualizing prior sensitivity across ranges of hyperparameter specifications (Franck and Gramacy, 2019; Sinharay and Stern, 2002).

Akaike information criterion

Akaike information criterion (AIC) is an information criteria-based relative fit index that was developed as an approximation of out-of-sample predictive accuracy of a model given the available data (Akaike, 1974). Like BIC, AIC's deviance term is based on the log-likelihood (also known as the log predictive density; Gelman et al., 2014) given the maximum likelihood point estimate $\hat{\theta}_{MLE}$. The formula for AIC is:

$$AIC = -2 \log p(x|\hat{\theta}_{MLE}) + 2k \quad (10)$$

In general, increasing the number of estimated parameters k increases the predictive accuracy of a model. Thus, the penalty term $2k$ is added as a correction for the increased predictive accuracy associated with additional estimated parameters. The correction for the number of estimated parameters, or effective number of parameters, however, presupposes linear models with normal posterior distributions. Moreover, the effective number of parameters may diverge from the number of estimated parameters when random effects (e.g., multilevel models) or informative prior information is specified, as the effective number of parameters is not clearly defined in these situations (Spiegelhalter et al., 2002). For a detailed illustration of this problem, see Gelman et al. (2014).

Interpretation of AIC is similar to BIC—and other information criteria-based indices—in that models with smaller values are preferred. The difference in penalty terms, however, results in AIC tending to prefer more complex models than BIC. Moreover, AIC tends to perform better with smaller sample sizes (Wasserman, 2000; c.f., Zhang, 1993). Despite the relative ease of interpretations, AIC and BIC are not generally recommended among Bayesian researchers (e.g., Gelman et al., 2013). A common criticism among Bayesian researchers is AIC and BIC are not generally considered fully-Bayesian approaches, as the uncertainty of the posterior distribution is not accounted for in their computations. Bayesian researchers have thus pursued relative model-data fit indices that account for the uncertainty associated with Bayesian methodology.

Deviance information criterion

Deviance information criterion (DIC) was developed as a partially Bayesian generalization of AIC that accommodates multilevel models and non-flat (i.e., informative) prior specifications (Spiegelhalter et al., 2002). DIC is analogous to other information criteria-based indices in that it is expressed as a sum of a deviance and a penalty term, and smaller values are preferable when comparing models. However, the deviance is function of the posterior mean $\hat{\theta}_{EAP}$ rather than $\hat{\theta}_{MLE}$ and thus DIC does not perform well when the posterior is not well summarized by the mean. That is, for posteriors that are not symmetric and unimodal, DIC may not be an effective criteria for evaluating relative fit.

The effective number of parameters is based on posterior estimates of model parameters. Specifically, it is the difference between the posterior mean of the deviance and the deviance of the posterior means of the parameters. An important consideration often relevant to educational researchers using models with latent variables, such as multilevel, IRT, and structural equation models (SEM), is the conditional versus marginal likelihood DIC definition (Zhang et al., 2019). The two definitions of the likelihood are concerned with the parameters of focus to the researcher. That is, the conditional likelihood DIC definition (DIC_C) is relevant when the latent variable parameters are of focus, and the marginal likelihood DIC definition (DIC_M) is relevant when the latent variables are not of focus (Merkle et al., 2019; Spiegelhalter et al., 2002). Merkle et al. (2019) provide a detailed comparison of these and other indices and illustrate the differential results obtained when the two definitions of DIC are used for model comparison.

DIC is among the most frequently used and widely implemented relative fit indices in Bayesian psychometric software. Given the two definitions of DIC can give disparate results, researchers should be careful to note which definition is implemented in their software of choice. DIC_C is currently implemented in BUGS (Lunn et al., 2012), JAGS (Plummer, 2003), the SAS MCMC procedure (SAS Institute Inc., 2018), and Stan (Stan Development Team, 2019), and DIC_M is currently implemented in blavaan (Merkle and Rosseel, 2018) and Mplus, (Muthén and Muthén, 1998–2017).

For brevity, we will limit our discussion to the DIC_C definition. The deviance term associated with DIC_C is minus 2 times the natural log of the likelihood conditional on the model and latent variables:

$$Deviance = -2 \log p_C(x|\hat{\theta}_{EAP}, \hat{\omega}_{EAP}) \quad (11)$$

where $\hat{\omega}_{EAP}$ represents the latent variables. With respect to DIC_C , the effective number of parameters p_{DIC} is expressed as:

$$p_{DIC} = -2 \left(\log p_C(x|\hat{\theta}_{EAP}, \hat{\omega}_{EAP}) + E_{x|\theta, \omega}(\log p_C(x|\theta, \omega)) \right) \quad (12)$$

where the first term is the log predictive density given the posterior parameter means and the second term is the expected value of the log predictive density. In practice, this expectation is computed as follows:

$$E_{x|\theta, \omega}(\log p_C(x|\theta, \omega)) = \frac{1}{S} \sum_{s=1}^S \log p_C(x|\theta^{(s)}, \omega^{(s)}) \quad (13)$$

where S represents the number of simulations, $s = 1, 2, \dots, S$. This use of the full posterior is why some consider DIC a partially Bayesian fit index. Of note, the computation of DIC_M follows the same general formula except the latent variables ω have been integrated out. The definition of DIC is further complicated when used in the context of multilevel latent variable models and multilevel models with greater than two levels, as the level in which the marginalization occurs must be carefully considered. Further discussion regarding the conditional versus marginal likelihood choice can be found in Millar (2009) and specifically applied to psychometric models by Merkle et al. (2019) and Zhang et al. (2019).

Watanabe-Akaike information criterion

Watanabe-Akaike information criterion (WAIC), or widely applicable information criterion, is a more fully-Bayesian approach to estimating out-of-sample predictive accuracy (Watanabe, 2010). Given the applicability to multilevel and latent variable models, conditional versus marginal likelihood definitions must be considered. Although WAIC is considered a more novel relative fit index for Bayesian inference, its use in educational measurement is somewhat limited. When it is used, the conditional versus marginal WAIC definition is often not detailed (Revuelta and Ximénez, 2017). Luo and Al-Harbi (2017); Luo (2017); da Silva et al. (2019); and Qu et al. (2020) have demonstrated the use of $WAIC_C$ in IRT, and Lu et al. (2017) demonstrated the use of $WAIC_M$ in factor analysis. Merkle et al. (2019) illustrate both likelihood definitions, along with its DIC analogs, and discuss implications for choosing among the indices.

WAIC is considered a more fully-Bayesian fit index because both the deviance and penalty terms account for the full posterior distribution. The deviance term for the conditional WAIC definition ($WAIC_C$) is computed by using the log pointwise predictive density:

$$Deviance = -2 \sum_{j=1}^J \sum_{i=1}^N \log \left(\frac{1}{S} \sum_{s=1}^S p(x_{ji}|\theta_j^{(s)}, \omega_i^{(s)}) \right) \quad (14)$$

for items $j = 1, 2, \dots, J$ and persons $i = 1, 2, \dots, N$. The penalty term p_{WAIC} is then computed as the sum of the posterior variances of the log pointwise predictive density for each data point:

$$p_{WAIC} = \sum_{j=1}^J \sum_{i=1}^N Var(\log p(x_{ji}|\theta_j, \omega_i)) \quad (15)$$

This definition makes clear why the WAIC is often considered a more fully Bayesian method of model comparison as it accounts for the uncertainty in the posterior distribution rather than strictly a point estimate of the posterior.

Leave-one-out cross validation

A more recent model comparison index introduced to educational research is the Bayesian leave-one-out cross validation approximation (LOOCV; Watanabe, 2010). LOOCV is a fully Bayesian method that accounts for the uncertainty of the posterior distribution and provides an estimate of out-of-sample predictive accuracy. WAIC and LOOCV are asymptotically equivalent (Watanabe, 2010); however, little is known about their performance in educational research (for examples, see Lu et al., 2017; Revuelta and Ximénez, 2017). Like DIC and WAIC, conditional versus marginal likelihood definitions of LOOCV must be considered. Merkle et al. (2019) discuss the connection among conditional and marginal definitions of WAIC and LOOCV and their implications. Interested readers are further referred to Gelman et al. (2013) and Vehtari et al. (2017).

Given the relatively recent appearance of WAIC and LOOCV in educational and psychometric research, there is little known regarding the relative performance of DIC, WAIC, and LOOCV and even less known with respect to their conditional and marginal likelihood definitions. Luo and Al-Harbi (2017) found $WAIC_C$ performed better than AIC, BIC, DIC_C , and similar to $LOOIC_C$ when selecting the best dichotomous IRT model. However, findings were mixed when AIC, BIC, DIC_C , and $LOOCV_C$ were used to select the best polytomous IRT model (Luo, 2017). Moreover, there have been mixed findings comparing relative performance of DIC_C and $WAIC_C$ applied to growth IRT models (Qu et al., 2020), and when comparing DIC, WAIC, and LOOCV applied to multidimensional polytomous IRT models (Revuelta and Ximénez, 2017).

Educational measurement example

Returning to the 1PL and 2PL models fit to the LSAT6 data, $WAIC_C$ and $LOOCV_C$ estimates were obtained from the R package loo (Vehtari et al., 2017). The smaller obtained $WAIC_C$ value indicated the 1PL model ($WAIC_C = 4903.20$) fit the data better than the 2PL model ($WAIC_C = 4910.60$). Note, however, some posterior variances of the log pointwise predictive density used in the calculation of p_{WAIC} were greater than 0.40 and thus the approximation of the effective number of parameters may be unreliable (Vehtari et al., 2017). Nonetheless, the smaller value of $LOOCV_C$ further supported the better fit of the 1PL model ($LOOCV_C = 4907.10$) compared to the 2PL model ($LOOCV_C = 4922.00$).

Introduction

Subscores are scores based on subsections of a test. For example, scores on the algebra and geometry sections on a mathematics test or physical and human geography sections on a geography test could be reported as subscores. Brennan (2012) stated that users of test scores often want (indeed demand) that subscores be reported, along with total test scores, due to their potential diagnostic, remedial and instructional benefits. According to the National Research Council report "Knowing What Students Know" (2001), the purpose of assessments is to provide information about an examinee's knowledge, skills, and abilities and subscores may have the potential to provide such information. Furthermore, the US Government's No Child Left Behind (NCLB) Act of 2001 and Every Student Succeeds Act (ESSA; Every Student Succeeds Act, 2015–2016) require that state assessments provide more detailed and formative information. In particular, the latter act requires that state assessments "produce individual student interpretive, descriptive, and diagnostic reports" (p. 26); subscores might be used in such a diagnostic report. Thus, it seems quite obvious that there is substantial pressure on testing programs to report subscores, both at the individual (e.g., test taker) and aggregate (e.g., institution) levels. It is therefore not surprising that subscores are reported by several large-scale testing programs, such as SAT[®], ACT[®], Praxis, and LSAT.

In the next section, we provide a review of the literature on how subscores are typically reported and on recommendations regarding how they ought to be reported. This review is followed by a section on the quality of subscores, which includes a discussion of how existing subscores often do not have satisfactory psychometric properties. Then we include a section on techniques to evaluate the quality of subscores and a review of the existing analyses of their quality. A real data example is provided in the penultimate section. The final section includes several conclusions and recommendations.

Subscore reporting: current practice and recommendations

Fig. 1 shows an example of one section of a sample Praxis[®] test taker score report (the report can also be found at https://www.ets.org/s/praxis/pdf/sample_score_report.pdf). A total of five subscores with maximum possible values ranging from 15 to 37 are reported for this test that has the title *Praxis Elementary Education: Curriculum, Instruction, and Assessment*. The average range of subscores earned by the middle 50% of test takers is reported and can be used to compare how well an examinee did versus the other test takers who took this test. Fig. 2 shows an example of a portion of a sample institutional subscore report for an assessment designed to measure critical thinking. The subscore report is intended to enable institutions to compare their mean scaled scores with the mean scaled scores of the institutions in the comparison group. Reports like those shown in Figs. 1 and 2 might be useful to assess examinees' or institutions' specific strengths and weaknesses in different sub-content areas. However, operational score reports often provide the word of caution that these subscores are based on a small number of items and are less reliable than the official scaled scores. See Fig. 1 for an example.

Goodman and Hambleton (2004) provided a comprehensive review and critique of score reporting practices from 16 large-scale assessments offered by US states and Canadian provinces and commercial testing companies. Figures 17–21 of Goodman and Hambleton (2004) provide examples of several operational score reports that include subscores. The subscores in the score reports examined by them were reported in one of three forms—number-correct or raw scores, percent-correct scores, or percentile raw scores.

Goodman and Hambleton (2004) identified the following problems in the score reports that they examined: (a) reports that assume a high level of statistical knowledge on part of the users, (b) use of statistical jargon such as "statistical significance" or

Test / Test Category *	Your Raw Points Earned	Average Performance Range **
ELEMENTARY EDUCATION: CURRICULUM, INSTRUCTION, AND ASSESSMENT (5017)		
I. READING AND LANGUAGE ARTS	33 out of 37	23–29
II. MATHEMATICS	26 out of 31	19–25
III. SCIENCE	15 out of 20	11–15
IV. SOCIAL STUDIES	14 out of 17	9–13
V. ART, MUSIC, AND PHYSICAL EDUCATION	13 out of 15	8–12

* Category-level information indicates the number of test questions answered correctly for relatively small subsets of the questions. Because they are based on small numbers of questions, category scores are less reliable than the official scaled scores, which are based on the full sets of questions. Furthermore, the questions in a category may vary in difficulty from one test to another. Therefore, the category scores of individuals who have taken different forms of the test are not necessarily comparable. For these reasons, category scores should not be considered a precise reflection of a candidate's level of knowledge in that category and ETS recommends that category information not be used to inform any decisions affecting candidates without careful consideration of such inherent lack of precision.

** The range of scores earned by the middle 50% of a group of test takers who took this form of the test at the most recent national administration or other comparable time period. N/C means that this range was not computed because fewer than 30 test takers took this form of the test or because there were fewer than 8 questions in the category or, for a constructed-response module, fewer than 8 points to be awarded by the raters. N/A indicates that this test section was not taken and, therefore, the information is not applicable.

Fig. 1 A sample *Praxis*® test taker subscore report. Reproduced with permission from https://www.ets.org/s/praxis/pdf/sample_score_report.pdf.

The chart below enables you to compare the mean scaled scores for your Reporting Group with the mean scaled scores of the institutions in the Comparison Group.

The number in the dark rectangle is the mean scaled score of your Reporting Group. The figure below is a "box-and-whisker" graph of the mean scores of the institutions in the Comparison Group. The yellow bar (the "box") shows the range of the middle 50% of the institutions. The black horizontal lines (the "whiskers") extend to the range of the middle 80%. The vertical line through the box indicates the median — the point that separates the upper half of the institutions from the lower half. The black dot indicates the mean of the institutions' mean scores.

OVERALL SCALED SCORES (Scale of 150–180)

SUBSCORES (Scale of 1–10)

Fig. 2 Sample institutional subscore report for an assessment measuring critical thinking. Reproduced with permission from <https://www.ets.org/s/heighten/pdf/critical-thinking-sample-institutions-score-report.pdf>.

"standard error" that confused and often intimidated the users, (c) misunderstanding or ignoring of technical symbols, concepts and footnotes by the users of score reports, (d) reports that provided too much information that made it difficult for users to extract what they needed most, (e) including excessively dense graphics and displays that were daunting for readers, and (f) lack of descriptive information such as definitions and examples to aid interpretation of the results. Even in the examples provided in Figs. 1 and 2, audience without basic statistical knowledge might fail to understand some of the text provided such as "scaled score" and "box and whisker plots." Further details on more recent score-reporting practices and recommendations on how to improve upon them can

be found in [Rick and Park \(2017\)](#) who extended the findings of [Goodman and Hambleton \(2004\)](#) through an investigation using recent score reports from 23 US States and one US territory, and also in [Tannenbaum \(2018\)](#), [Slater et al. \(2018\)](#), [Zapata-Rivera et al. \(2012\)](#), and [Zenisky and Hambleton \(2012\)](#). The practices and recommendations in the aforementioned reports primarily relate to score reports for the overall test scores but several of them relate to subscores as well.

[Roberts and Gierl \(2010\)](#) noted that integration and application of interdisciplinary techniques from education, information design (e.g., [Pettersson, 2002](#)), and technology are required for effective score reporting. They provided guidelines for reporting and presenting diagnostic scores originating from cognitive diagnostic assessments (see the article on cognitive diagnostic models by Bradshaw in this encyclopedia) based on a review of educational score reporting practices and literature from the area of information design and presented a sample diagnostic report to illustrate their approach. Because subscores constitute a type of diagnostic score, several recommendations of Roberts and Gierl apply to subscore reporting as well. For example, their sample diagnostic report included three sections: (a) a top section contained an overview of the contents of the report, (b) the middle section contained diagnostic information along with item-level performance, and (c) the bottom section contained a narrative summary of the examinee's performance across all the subareas. A score report that is supposed to include information on subscores could consist of similar sections as in Roberts and Gierl; for example, the middle section could include diagnostic information (obtained from the subscores) along with item-level performance.

Psychometric quality of subscores: a descriptive discussion

Despite the demand for and apparent usefulness of subscores, they need to satisfy certain professional standards in order for them to be reported. According to [Haberman \(2008\)](#), a subscore may be reported if it has high reliability and it is distinct from the other subscores. Similarly, [Tate \(2004\)](#) has emphasized the importance of ensuring reasonable subscore performance in terms of high reliability and validity to minimize incorrect instructional and remediation decisions. These concerns agree with Standards 1.14 and 2.3 of *Standards for Educational and Psychological Testing* ([American Educational Research Association et al., 2014](#)) that require proof of adequate reliability (see the article on the topic by Chajewski in this encyclopedia), validity (see the article on the topic by Lane in this encyclopedia), and distinctness of subscores. [Monaghan \(2006\)](#) pointed out that "While they want to be responsive to the desires of the educational marketplace, testing organizations are also very concerned about the appropriate use and interpretation of subscores." Just as inaccurate information at the total test score level may lead to decisions with damaging consequences (e.g., wrongly certifying someone to be a health care professional), inaccurate information at the subscore level can also lead to incorrect remedial decisions resulting in large and needless expenses for examinees, states, or institutions ([Sinharay et al., 2011](#)). Moreover, if subscores are used in combination with total scores for high-stakes purposes such as hiring or certification, then the consequences of using subscores of inadequate psychometric quality (i.e., low reliability and validity) can be especially damaging.

Low reliabilities of subscores on educational tests are common because these subscores are often based on only a few items. For example, the score report shown in Figure 20 of [Goodman and Hambleton \(2004\)](#) includes seven subscores that are based on only five items each. Such subscores are most often outcomes of retrofitting, where reporting subscores was not a primary goal but subscores were later provided to comply with clients' requests for more diagnostic information on examinees. Furthermore, as [Sinharay and Haberman \(2008\)](#) pointed out, real data may not provide information as fine-grained as suggested or hoped for by the assessment specialist. A theory of response processes based on cognitive psychology may suggest several skills, but a test includes a limited number of items and the test may not have enough items to provide adequate information about all of these skills. For example, for the iSkills™ test (e.g., [Katz et al., 2008](#)), an expert committee identified seven performance Information and Communications Technology literacy skills. However, an exploratory factor analysis (e.g., [Tukey, 1977](#); also see the article by Trendafilov on this topic in this encyclopedia) of the data revealed only one factor and confirmatory factor models (e.g., [Gorsuch, 1983](#); also see the article by Price on confirmatory factor analysis in this encyclopedia) in which the factors corresponded to performance areas or a combination thereof did not fit the data any better than a 1-factor solution ([Katz et al., 2008](#)). As a result, only an overall Information and Communications Technology literacy score was reported. Clearly, a testing practitioner attempting to report subscores has to make an informed judgment on how much evidence the data can reliably provide and report only as much information as is reliably supported.

If subscores are used as diagnostic tools, then the consequences of using subscores are less severe compared to those of using scores for high stakes use such as certification. Nevertheless, subscores should at least be moderately reliable (e.g., 0.80 or higher, a cutoff that seems reasonable from [Nunnally, 1978](#), p. 245) to be of any remedial use. Otherwise, users would mostly be chasing noise and making incorrect remedial decisions. Even when the subscore reliabilities are high, reporting subscores is not automatically justified if the subscores do not provide unique and additional information than what is already provided by the total score or the other subscores.

There are several statistical techniques, starting from fairly basic statistical operations such as computing correlations and reliabilities to more sophisticated analyses such as factor analysis and dimensionality analysis using specialized software such as DIMTEST ([Stout, 1987](#)) and DETECT ([Kim, 1994](#)), which have been used to assess whether the subscores are worth reporting. Some of these techniques are briefly reviewed in the next section.

Methods to evaluate when subscores are worth reporting

Use of correlation or reliability of subscores

Researchers and practitioners often use simple rules to determine if subscores are worth reporting. Several researchers have used the correlations corrected for attenuation due to unreliability (see, for example, [Crocker and Algina, 1986](#), p. 237) between the different

subscores to decide whether it is reasonable to report subscores. Fairly large disattenuated correlations among subscores essentially indicate that the subscores are not distinct from each other and therefore are not worth reporting. For example, [McPeck et al. \(1976\)](#) and [Haladyna and Kramer \(2004\)](#) used the criterion that reporting of subscores is not warranted if the correlations corrected for attenuation among them are larger than 0.90. Similarly, researchers often judge the subscores to be useful only if their reliabilities are sufficiently large. For example, [Wainer et al. \(2001, p. 363\)](#) commented that the subscores for three of the four sections of the item tryout administration of the North Carolina Test of Computer Skills are insufficiently reliable to allow individual student reporting.

Application of principal component analysis and factor analysis

A simple approach to evaluate whether the subscores are distinct enough involves the computation of the eigenvalues from the correlation matrix among the subscores (or from the correlation matrix among the items) in a principal component analysis (e.g., [Hotelling, 1933](#); also see the article by [Trendafilov](#) on this topic in this encyclopedia). If, for example, for a data set that involves 5 hypothesized subscores, four of the five eigenvalues computed from the 5×5 correlation matrix of the subscores are smaller than 1 or if a plot of the eigenvalues in a decreasing order shows that the eigenvalues abruptly level out after one or two subscores, then the claim of five distinct subscores is not justified. On the contrary, the presence of five large eigenvalues would support the reporting of the five subscores. [Sinharay et al. \(2007\)](#) computed the eigenvalues from the 6×6 correlation matrix of 6 reported subscores from two forms of a test for paraprofessionals. They found that the largest eigenvalue was 4.3 for both forms while the remaining 5 eigenvalues were smaller than 0.5, suggesting that the test was unidimensional. Although the test was developed with the intention of measuring knowledge and skills in 6 distinct subareas, analysis of the data justified the reporting of a single composite score and not 6 distinct subscores. Similarly, [Stone et al. \(2010\)](#) reported, using an exploratory factor analysis of the inter-item correlation matrix, the presence of only one factor in the Eighth Grade Mathematics portion of the Spring 2006 assessment of the Delaware State Testing Program; hence, subscores were not worth reporting for the assessment.

Application of the beta-binomial model

[Harris and Hanson \(1991\)](#) suggested the approach of fitting the beta-binomial model ([Lord, 1965](#)) to the observed subscore distributions to determine if the subscores have added value over and beyond the total score. Consider a test with two purported subscores. If the subscores are not distinct, then their corresponding true subscores are functionally related. In this approach, one computes the hypothetical bivariate distribution of the two subscores under the assumptions that (a) their corresponding true subscores are functionally related, and that (b) the distributions of the subscores can be modeled by the four parameter beta binomial model ([Lord, 1965](#)). Rejection of the null hypothesis that this hypothetical bivariate distribution fits the observed bivariate distribution of the two subscores would provide evidence of the distinctness of the subscores. Harris and Hanson used a χ^2 -type statistic to determine the goodness of fit of the hypothetical bivariate distribution of the two subscores to the observed bivariate distribution of subscores. However, the method of Harris and Hanson involves significance testing with a chi-square statistic whose null distribution is not well established.

Fitting of multidimensional item response theory models

One can examine if subscores have added value by fitting a multidimensional item response theory (MIRT) model (e.g., [Reckase, 1997](#); [Ackerman et al., 2003](#); see also the article by [Cai](#) on these models in this encyclopedia) to the data. MIRT is a tool to model examinee responses to a test that measures more than one ability, for example, a test that measures both mathematical and verbal ability. In MIRT, the probability of a correct item response is a function of several abilities, rather than a single measure of ability. If subscores have added value, then a statistical test of model fit should indicate a better fit when a MIRT model instead of an unidimensional IRT model (see the article by [Ackerman et al.](#) on unidimensional IRT models in this encyclopedia) is applied to the data as long as the sample size is not too small. See, for example, [Sinharay \(2019\)](#) for a demonstration of this sort of use of MIRT.

Using dimensionality assessment software such as DETECT and DIMTEST

The DETECT software ([Zhang and Stout, 1999](#)) uses an algorithm that searches through all of the possible partitions of items into clusters to find the one that maximizes the DETECT statistic that was suggested by [Kim \(1994\)](#). The data can be considered to be unidimensional if the DETECT statistic is less than 0.10. Values between 0.10 and 0.50 would indicate a weak amount of multidimensionality, values between 0.51 and 1.00 would indicate a moderate amount of multidimensionality, and values higher than 1.00 would indicate high level of multidimensionality ([Kim, 1994](#)). The use of the DIMTEST software ([Stout, 1987](#)) involves the assessment of the statistical significance of the possible dimensional distinctiveness between two specified subtests (the Assessment Subtest or AT and the Partitioning Subtest or PT, which are supposed to measure different composite abilities if the test is multidimensional). The test statistic T calculated by DIMTEST represents the degree of dimensional distinctiveness between these two specified subsets. For example, if the testing practitioner wants to know if an Economics test has distinct dimensions such as macro or micro economics that are dimensionally distinct from the rest of the items in the test, then the macro (or micro) items can form the assessment subtest and the remaining items can form the partitioning subtest; then, a significant value of the DIMTEST index T would indicate that the two subsets are dimensionally distinct.

Application of Haberman's classical test theory based method

Haberman (2008) suggested a method based on classical test theory (see the article by Chajewski in this encyclopedia) to determine if a subscore has added value. According to the method, a subscore has added value only if it can be predicted better by the corresponding subscore on a parallel form than by the total score on the parallel form (Sinharay, 2013). To apply the method, one examines whether the reliability of a subscore is larger than another reliability-like measure referred to as the proportional reduction in mean squared error (PRMSE) of the total score. Like the reliability coefficient, the PRMSE ranges between 0 and 1 with 0 and 1 indicating the lowest and highest degrees of trustworthiness, respectively. Using the Haberman method, a subscore has added value and may be considered worth reporting only when the subscore reliability is larger than the PRMSE of the total score, which happens if and only if the observed subscore predicts the true subscore more accurately than does the observed total score.

Sinharay et al. (2007) discussed why the strategy suggested by Haberman is reasonable and how it ensures that a subscore satisfies professional standards. Conceptually, if the subscore is highly correlated with the total score (i.e., the subscore and the total score measure the same basic underlying skill), then the subscore does not provide any added value over what is already provided by the total score. A subscore is more likely to have added value according to the method of Haberman if it has high reliability and if it is distinct from the other subscores. Applications of the Haberman method can be found in Lyren (2009), Puhan et al. (2010), Meijer et al. (2017), Sinharay (2010, 2019), Sinharay et al. (2010), and Sinharay et al. (2011). For example, Sinharay et al. (2011) analyzed data from a teacher certification test with four subscores. They found the values of the reliabilities of the subscores to be 0.71, 0.85, 0.67, and 0.72, for the reading, math, social studies and science subscores, respectively. The corresponding values of the PRMSE for the total score are 0.72, 0.76, 0.74, and 0.79, respectively. Thus, only the mathematics subscore of the test had added value. Similar results were also reported by Puhan et al. (2010) for several other teacher certification tests.

How often do subscores have adequate psychometric quality: a brief review of existing research

In the previous subsection, we presented methods that can be used to examine the psychometric quality of subscores to determine if they are worth reporting. In this subsection, we will present research that shows how often subscores have adequate psychometric quality so that they can be considered worth reporting. Both operational and simulated data were used in these studies.

Sinharay (2010) performed an extensive survey regarding whether subscores have added value over the total score using the Haberman (2008) method. He used data from 25 large-scale operational tests (e.g., P-ACT+ English, P-ACT+ Math, SAT Verbal, SAT Math, SAT, SweSAT, Major Field Test in Business, etc), several of which reported subscores operationally. Of the 25 tests, sixteen had no subscores with added value according to the method of Haberman. Among the remaining nine tests, all of which had at least an average of 24 items contributing to each subscore, only some of the subscores had added value. Sinharay also performed a detailed simulation study to find out when subscores can be expected to have added value. The simulation study showed that in order to have added value, subscores have to be based on a sufficient number of (roughly 20) items, and be sufficiently distinct from one another—the disattenuated correlation between subscores has to be less than about 0.85.

Similarly, from various types of analyses, subscores were found to have little added value by Stone et al. (2010) for the 2006 eighth-grade Delaware Math Assessment, Harris and Hanson (1991) for the P-ACT+ examination, Wainer et al. (2001) for the Just-in-Time Examination conducted by the American Production and Inventory Control Society certification, Wainer et al. (2000) for the Education in the Elementary School Assessment, and Ackerman and Shu (2009) for a fifth grade end-of-grade assessment.

These studies collectively indicate that subscores on operational tests have most often been found to not satisfy professional standards.

A real data example

Some of the abovementioned approaches are demonstrated using a data set that was considered in Dai et al. (2017) and is from the 2011 administration of the Trends in International Mathematics and Science Study (TIMSS; Kastberg et al., 2013) eighth-grade mathematics assessments. TIMSS is used to assess achievement in countries around the world every four years; the assessment is used to collect a rich array of information about the educational contexts for learning mathematics and science (Mullis et al., 2004). The assessment is one of the most widely used large-scale assessments, and its public-use data are available for free. As described under the TIMSS 2011 Mathematics Framework, the following four content subscales were defined to specify the mathematics subject matter at the eighth grade: (1) number, (2) algebra, (3) geometry, and (4) data and chance. Due to the booklet design in TIMSS, students participating in the assessment were only administered a fraction (i.e., a booklet) of the total item pool. In this article, data from Booklet 11 that includes two blocks (M11 and M12) were utilized. The data contained responses from 765 students to 32 items with 6–9 items on each of the four subscales. Omitted responses were treated as incorrect. Note that although individual-level subscores are considered in the analysis here, TIMSS is not designed to report individual-level scores or subscores.

Table 1 shows the correlation coefficients (above the diagonal), deattenuated correlations (below the diagonal), and the reliabilities (Cronbach's alpha; diagonals) of the four subscores. The table shows that the subscores have low to moderate reliabilities that range between 0.57 and 0.68. The correlation coefficients range between 0.51 and 0.65 while the disattenuated correlations range between 0.75 and 0.96—so several disattenuated correlations are smaller than 0.90. Table 2 shows the reliability and the PRMSE for the total score for each subscore. The latter quantity is larger than the former for each subscore, which indicates that none of the four

Table 1 Correlation coefficients (above the diagonal), deattenuated correlations (below the diagonal, in bold font), and the reliabilities (diagonals,) of the four subscores for the TIMSS data.

	<i>Number</i>	<i>Algebra</i>	<i>Geometry</i>	<i>Data and chance</i>
Number	0.68	0.57	0.56	0.65
Algebra	0.84	0.67	0.52	0.51
Geometry	0.89	0.83	0.57	0.54
Data & chance	0.96	0.75	0.86	0.68

subscores has added value. Annotated R code that can be used to perform the computations that produced the values in [Tables 1](#) and [2](#) are provided in [Fig. 3](#). The R package “subscore” ([Dai et al., 2019](#)) was used to perform the computations. [Fig. 3](#) also includes the R code for using the R package *mirt* ([Chalmers, 2020](#)) to determine if the subscores have added value; in this analysis, a 4-dimensional IRT model did not fit the data better than a unidimensional IRT model, which supports the results from the Haberman method that the subscores do not have added value.

Conclusions and recommendations

While subscores are highly sought after by test users and are reported operationally for several large-scale assessments, operationally reported subscores often lack adequate psychometric quality. Researchers such as [Goodman and Hambleton \(2004\)](#) and [Sinharay \(2010\)](#) provided examples of several operational tests for which reported subscores are based on too few items and/or do not have added value.

While the use of content blueprints as a basis for defining subscore structure does not necessarily guarantee that the different subscores will produce highly distinct subscores, the use of psychometric approaches as a basis of constructing subscore structure

might be more useful. For example, Reckase and Xu (2014) suggested an approach based on MIRT to identify the subscore structure for a data set. However, psychometric-based approaches may lead to subscores that would be difficult to interpret. In addition, such subscores may not be reproducible when applied to other data.

Subscores should be reported only when there is sufficient evidence of adequate reliability, validity and distinctiveness of the subscores. Any reported subscore, in order to be reliable, should be based on a sufficient number of carefully constructed items. Although there are no clear guidelines in the psychometric literature on how many items are needed to provide a reliable subscore, some research has shown that at least 20 multiple-choice items are typically needed in each subtest for the corresponding subscore to yield a moderately high reliability (e.g., Puhan et al., 2010; Sinharay, 2010). Combining some subscores can increase subdomain test length and therefore might result in subscores that have higher reliability and hence added value. For example, subscores for “Physics: theory” and “Physics: applications” may be combined to yield one subscore for “Physics.” Combining subscores to meet reliability considerations, however, can create interpretation problems. For given lengths of a test and its component subtests, it is possible to increase subscore reliability by having some items measure two subdomains. But common items may make the two corresponding subscores more related and therefore less useful for diagnostic purposes. It is also important to ensure that the skills of interest are as distinct as possible from each other, though this is quite a difficult task to accomplish before seeing the data.

Although we primarily discussed subscores for individual examinees, subscores can be reported at an aggregate level as well (e.g., institution or district levels). Longford (1990) and Haberman et al. (2009) have suggested methods to examine whether aggregate-level subscores are of added value, and presented examples of situations when aggregate-level subscores do not have added value. They also presented examples where it is not justified to report a subscore for individual examinees, but it is justified to report averages of that subscore for groups of examinees.

Testing programs employ a range of tools including innovative test design, use of identification procedures and biometric data to authenticate examinees, and proctoring to prevent, deter, and impede cheating on educational tests. Despite the testing programs' best efforts, examinees manage to successfully cheat on these tests (Wollack and Schoenig, 2018). In fact, numerous recent instances of fraud on educational tests (e.g., Jacob and Levitt, 2003; Maynes, 2013) severely undermine the integrity of the test results. While various types of fraudulent behavior have been observed, Wollack and Schoenig (2018) divided the types of fraudulent behavior into three main types: (a) test tampering, (b) answer-copying and collusion and (c) item preknowledge.

Standard 6.6 of the *Standards for Educational and Psychological Testing* (American Educational Research Association [AERA] et al., 2014) includes the recommendation among others that testing programs with high-stakes consequences should have defined procedures for detecting potential testing irregularities. Some guidelines on methods for detecting fraudulent behavior on tests can be found in a special report on testing and data integrity published by NCME (2012).

Naturally, there is a growing interest in statistical/psychometric methods for detecting fraudulent behavior on tests, which is evident from the publication of several edited volumes (Cizek and Wollack, 2017; Kingston and Clark, 2014; Wollack and Fremer, 2013) and numerous journal articles, book articles, and conference presentations (e.g., Allen and Ghattas, 2016; McLeod et al., 2003; Sinharay, 2017; 2018a; 2018b; Sinharay et al., 2017; van der Linden, 2009; van der Linden and Guo, 2008; van der Linden and Lewis, 2015; van der Linden and Sotaridona, 2006; Wollack et al., 2015; Wang et al., 2017; Wollack and Schoenig, 2018) on the topic. Note that these recent publications add to several often-cited publications on the topic from the previous millennium and early in this millennium (e.g., Buss and Novick, 1980; Karabatsos, 2003; Lewis and Thayer, 1998; van der Linden and van Krimpen-Stoop, 2003; Wollack, 1997). Summaries of some of the statistical/psychometric methods presented in these publications can be found in, for example, Ferrara (2017) and He et al. (2020). Most of the statistical approaches for detection of test fraud employ item response theory (IRT) models (e.g., de Ayala, 2009; Hambleton and Swaminathan, 1985, and the Item Response Theory (Unidimensional) article in this volume) to model the item scores and some of the approaches employ response-time models (RTMs; e.g., De Boeck and Jeon, 2019; van der Linden, 2016, and the Response Time Modeling article in this volume).

The goal of this paper is to provide a brief review of the statistical/psychometric methods for detecting fraud on educational assessments that are embodied in the aforementioned publications. Brief descriptions are provided of score differencing, analysis of erasures and answer changes, similarity analysis, person-fit analysis, and use of response-time models, which are the five main types of statistical/psychometric methods for detecting test fraud. Only the underlying concepts and principles behind the various statistical methods are provided. The mathematical descriptions of the methods are not described and can be found in the original references that are provided. Several real data examples demonstrate how to apply some of these methods.

The types of test fraud and the statistical approaches to detect them

Wollack and Schoenig (2018) divided the types of test fraud that are common in educational tests into the three following main types:

- *Test tampering*: In its most common form, classroom teachers or administrators change student answers after the tests are complete (e.g., Wollack et al., 2015). Although less common, test tampering can take place on computerized tests as well.

Table 1 The three types of test fraud and five types of statistical approaches to detect them.

Approaches	Test tampering	Answer-copying and collusion	Item preknowledge
Score differencing	✓		✓
Analysis of erasures and answer changes	✓		
Copying-detection and similarity analyses		✓	
Person-fit analysis	✓	✓	✓
Use of response-time models		✓	✓

- *Answer-copying and collusion*: Examinees often copy answers from other examinees, most often those sitting close to them. Collusion involves two or more examinees working together (when they are not allowed to) to answer the test items.
- *Item preknowledge*: Examinees benefit from item preknowledge when a “source” (such as a teacher, a test preparation company, or a website) shares test questions and/or their answers and then several beneficiaries memorize the assessment questions and/or answers. The items that are shared are usually referred to as “compromised” items.

Wollack and Schoenig (2018) also noted the existence of five types of statistical/psychometric approaches to detect the three aforementioned types of fraud.

Table 1 shows the three types of test fraud (the column names) and the five types of statistical/psychometric approaches (row names) identified by Wollack and Schoenig (2018). A check mark for a cell indicates that the approach in the heading of the corresponding row can be applied to detect the type of fraud corresponding to that column. For example, a check mark for score differencing and test tampering indicates that score differencing can be used to detect test tampering.

The five main types of statistical approaches for detecting test fraud that were mentioned by Wollack and Schoenig (2018) are described below. A couple of the most popular approaches under each type are briefly mentioned as well. Various types of test fraud lead to various types of aberrance or irregularity in the examinee data. For example, multiple types of test fraud lead to a better performance on a subset of the test compared to the rest of the test (e.g., Sinharay and Jensen, 2019), answer-copying often leads to unusual similarity between the answer options chosen by pairs of examinees (e.g., Wollack, 1997), and most types of test fraud leads to a general misfit of an IRT model to the examinee data. Each statistical approach is designed to detect one type of irregularity caused by test fraud. For example, score differencing is designed to detect better performance on a subset of the test while person-fit analysis is designed to detect the misfit of an IRT model to the examinee data.

Score differencing

Score differencing involves a test of the null hypothesis of equal performance of an examinee over two sets of items, S_1 and S_2 . The alternative hypothesis is that the performance is better, presumably due to test fraud, on one of the item sets. To perform score differencing, one adopts an IRT framework and assumes that the true ability of the examinee on S_1 and S_2 respectively are θ_1 and θ_2 , respectively, and performs the null hypothesis $H_0: \theta_1 = \theta_2$. Score differencing can be used to detect several types of test fraud including item preknowledge (e.g., Sinharay, 2017) where the item sets S_1 and S_2 are the set of compromised items and the remaining items, and test tampering (e.g., Sinharay et al., 2017), where the item sets S_1 and S_2 are the set of items with erasures and the remaining items. Existing approaches for score differencing include (a) a variation of the optimal index (Drasgow et al., 1996), which is essentially the ratio of the likelihoods of an examinee under test fraud and that under no fraud, (b) the L_s statistic (Sinharay, 2017) that is a variation of the likelihood ratio test statistic for testing the null hypothesis $H_0: \theta_1 = \theta_2$, and (c) the predictive checking method (Wang et al., 2017) that involves the computation of a Bayesian p-value indicating the extremeness of the performance on the compromised items.

Analysis of erasures and answer changes

Erasure analysis gained prominence after the alleged educator cheating in 2009 in the public schools of the US city of Atlanta (e.g., Kingston, 2013). Erasures, or, in general, answer changes (that is a more appropriate term for computerized tests that allow answer changes), are found roughly for one out of every 50 answers irrespective of test fraud (e.g., Primoli et al., 2011). While most of these answer changes are benign (that is, not fraudulent), fraudulent answer changes arise when teachers or school administrators help students by correcting students' wrong answers on their answer sheets after the test, often to hide underachievement by their class or school (van der Linden and Lewis, 2015). In analysis of answer changes, an investigator attempts to find out if the answer changes are fraudulent. In 2013, as many as 33 US states reported using analysis of answer changes to detect possible fraudulent test-taking behavior in their K-12 assessments (Government Accountability Office, 2013). However, analysis of answer changes in several states involves only the use of the average wrong-to-right answer-change count for a school or school-district (e.g., Bishop and Egan, 2017, pp. 204–205), a statistic whose power has been shown to be rather low, that is, the statistic would fail to flag many cheaters (e.g., Sinharay, 2018b). Additional indices that have been suggested for performing analysis of answer changes include the erasure detection index (EDI; Wollack et al., 2015), EDI for groups of examinees (Wollack and Eckerly, 2017), the L-index (Sinharay et al., 2017), the posterior predictive p-value corresponding to the EDI (Sinharay and

Johnson, 2017), and extensions of the EDI for groups of examinees (Peng and Sinharay, 2020; Sinharay, 2018b). These indices mostly involve an examination of whether the examinees' performance on the items with answer changes is much better given the performance on the items with no answer changes—much better performance on the former items typically indicates that the answer changes are fraudulent. The EDI is the standardized value, computed under an IRT model, of the wrong-to-right answer-change count of an examinee and the L-index is a variation of the likelihood ratio test statistic (and is conceptually similar to the L_s statistic; Sinharay, 2017) for the null hypothesis that the examinee performance on the items with answer changes is the same as that on the items with no answer changes.

Copying-detection and similarity analyses

The goal of *copying-detection and similarity analyses* is to detect potential collusion among a pair or group of examinees by investigating the similarity of their answers and flagging the examinees who produce an observed number of answer matches that significantly exceeds the number of matches predicted under the model. A “match” in this context may refer to matching incorrect answers or to matching correct and incorrect answers. Copying-detection and similarity analyses are performed using *answer-copying indices* and *similarity indices*. While both of these two types of indices quantify the similarity of the answers of pairs of examinees, they differ in the way they are computed. In computing the answer-copying indices for a pair of examinees, one first specifies a source and a copier in the pair and computes the expected number of answer matches conditional on the estimated ability of the copier and the answer string of the source. In computing the similarity indices for a pair of examinees, one does not specify a source or a copier and computes the expected number of answer matches conditional on the estimated abilities of the pair of examinees.

The answer-copying indices that are most popular include the K-index (e.g., Holland, 1996), which, for a pair of examinees, is the chance of observing at least the observed number of matching incorrect responses if the pair were working independently, or the closely related probability of matching incorrect responses (PMIR; e.g., Lewis and Thayer, 1998) the ω index (Wollack, 1997) that is the standardized value of the number of matching responses; and the probability of observing at least the observed number of matching responses under the generalized binomial model if the examinee pair were working independently (van der Linden and Sotaridona, 2006). van der Linden and Lewis (2015) suggested an approach to compute the posterior odds of answer-copying between a pair of examinees, where

$$\text{posterior odds of answer-copying} = \frac{\text{posterior probability that answer-copying occurred}}{\text{posterior probability that answer-copying did not occur}}$$

The approach does not employ any existing answer-copying index and instead employs combinatorial expressions and a reformulation of the simple recursive algorithm of Lord and Wingersky (1984) for the calculation of the distribution of the number-correct score. The approach is computation-intensive, but they suggested an efficient recursive algorithm for the calculation of the posterior odds of answer-copying.

Maynes (2014) suggested the similarity index M4 that consists of the number of identical correct and the number of identical incorrect answers. The probability distribution of the statistic is assumed to follow a generalized trinomial distribution, where probabilities of matching responses are estimated using item response probabilities from the nominal response model (Bock, 1972). Wollack and Maynes (2017) suggested a similarity index that can be used to detect groups of test-takers engaged in collusion. The approach employs cluster-analysis methods (e.g., Everitt et al., 2011) in conjunction with the M4 index (Maynes, 2014) to find clusters of examinees whose responses are similar.

Person-fit analysis

In person-fit analysis, an investigator tries to determine whether the item scores of an examinee follows an IRT model. In the presence of cheating, the item scores usually do not follow an IRT model because, for example, an examinee who cheats may answer more difficult items correctly than what an IRT model predicts. There exist several indices for performing person-fit analysis—these are referred to as person-fit statistics. Meijer and Sijtsma (2001) provided a review of several of these indices. Popular person-fit statistics include the caution indices (Tatsuoka, 1984), the H^T statistic (Smith, 1986), the l_z statistic (Drasgow et al., 1985), and the l_z^* statistic (Snijders, 2001; Sinharay, 2016c).

Glas and Meijer (2003), Sinharay (2015) and Sinharay (2016a) suggested performing person-fit analysis using the Bayesian p -values or *posterior predictive p -values* (e.g., Gelman et al., 1996) corresponding to several person-fit indices. While their Bayesian approach is computation-intensive, the approach does not depend on asymptotic results, and, may lead to more satisfactory false positive rate and/or power compared to frequentist approaches.

Use of response-time models

While there exist several RTMs, the most popular of them, arguably, is the lognormal model for response times (LNMRT; van der Linden, 2006). Let t_i denote the response time of a randomly chosen examinee on item i , where $i = 1, 2, \dots, I$. Let us define

$$y_i = \log(t_i)$$

Under the lognormal model for response times (LNMRT; van der Linden, 2006), y_i , $i = 1, 2, \dots, I$, are independent given τ and

$$y_i | \tau \sim \mathcal{N}\left(\beta_i - \tau, \frac{1}{\alpha_i^2}\right) \quad (1)$$

where $\mathcal{N}(\mu, \sigma^2)$ denotes the normal distribution with mean μ and variance σ^2 . That is, the probability density function of y_i is given by

$$f(y_i | \tau, \alpha_i, \beta_i) = \frac{\alpha_i}{\sqrt{2\pi}} e^{-\frac{1}{2}\alpha_i^2(y_i - \beta_i + \tau)^2} \quad (2)$$

The parameter τ is the examinee's speed parameter; a larger value of the parameter results in smaller expected response times on all the items for the examinee. The parameter β_i is the time-intensity parameter for item i ; a larger value of the parameter results in larger expected response times for all examinees on the item. The parameter α_i is the discrimination parameter for item i ; a larger value of the parameter leads to more information on and hence smaller standard error of the examinee speed parameters.

The hierarchical/joint model of van der Linden (2007) involves the application of a model for response times in combination with an IRT model for the item scores. In applying the joint model, one typically assumes that

- the response time follows the lognormal model (LNMRT; van der Linden, 2006) defined above.
- the item scores follow an IRT model; the flexibility of the approach allows the use of any IRT model such as the 2-parameter logistic model (2PLM).

van der Linden and Guo (2008) suggested a Bayesian approach that employs the hierarchical model of van der Linden (2007). The examinee-item combinations whose observed response times are too extreme compared to the corresponding posterior predictive density according to the joint model are flagged. An examinee with too many flagged examinee-item combinations is flagged for possible fraudulent behavior. van der Linden (2009) suggested a bivariate lognormal model for the distribution of the response times on a test for a pair of examinees. The correlation parameter of the model indicates the degree to which the response-times of the pair are similar. Therefore, the estimated value of the correlation and a test of hypothesis about the correlation provides information on whether the pair of examinees were involved in collusion, which is one type of test fraud. Mariani et al. (2014) and Sinharay (2018c) respectively suggested a Bayesian and frequentist variations of an approach in which the LNMRT is employed and an aberrant behavior is flagged when the sum of squared standardized residuals is large. Wang et al. (2016) suggested a two-stage approach to detect fraudulent behavior; in the first stage, a mixture hierarchical model is fitted to both the item scores and response times to distinguish solution behavior from aberrant behavior; in the second stage, a Bayesian residual index is constructed to differentiate rapid guessing from fraudulent behavior. Fox and Mariani (2017) suggested a Bayesian approach to person-fit analysis that adopts the hierarchical modeling approach of van der Linden (2007); large posterior probabilities of aberrant item-scores, aberrant response times, or both indicate possible fraudulent behavior. Sinharay and Johnson (2020) suggested an approach to detect item preknowledge that also adopts the hierarchical modeling approach of van der Linden (2007); much better and faster performance on the compromised items, found from a statistical hypothesis test, indicates potential preknowledge.

Other analyses

There are several other types of analyses that have been suggested for detecting fraudulent behavior on tests. Such analyses include the matching of response patterns (e.g., Haberman and Lee, 2017) to detect key sharing among examinees, modified IRT models for detecting various types of test fraud (e.g., McLeod et al., 2003; Segall, 2002), and application of data mining methods to detect various types of cheating (Man et al., 2019; Toton and Maynes, 2018; Zopluoglu, 2019).

Software for detection of test fraud

While companies specializing on test security have their proprietary software packages for the detection of test fraud, there is a lack of publicly available software packages for the purpose, with the exception of the SIFT (Assessment Systems Corporation, ASC) software, the R (R Core Team, 2021) packages CopyDetect (Zopluoglu, 2018) and PerFit (Tendeiro et al., 2016), and the R function lzstarMix (Sinharay, 2016b).

Real data examples

In the following discussion, four data examples demonstrate the use of various statistical tools to detect various types of test fraud. Each tool/approach that is used in an analysis has been found to perform satisfactorily compared to competing approaches in comparison studies. For example, Example 2 involves the frequentist L-index that was found to perform satisfactorily compared to other frequentist statistics for erasure analysis by Sinharay et al. (2017).

Example 1: similarity analysis

A data set including the item scores of 1644 examinees on one form of an international credentialing examination was available. While about three-fourths of the examinees are from the USA, the other one-fourth are from 27 different countries, with India ($n = 159$) and Philippines ($n = 156$) being the most popular countries among them. The data set was analyzed in several articles of Cizek and Wollack (2017) including in Zopluoglu (2017) who computed the values of several answer-copying indices for all examinee pairs within each test center. The examinees took the test in a total of 326 test centers. The test form includes 170 operational items that are dichotomously scored. The credentialing organization that administers the examination identified 61 items on the form as compromised. The organization also flagged 48 individuals on the form as possible cheaters from a variety of statistical analyses and an investigative process that brought in other information. These 48 individuals can be treated as truly aberrant for all practical purposes because of the rigor of the investigative process. Six of these flagged individuals belonged to a specific test center (that was the test center for 27 examinees in the data set) referred to as TC1.

The nominal response model (NRM; Bock, 1972) was fit to the data using the R package mirt (Chalmers, 2012). The ω index (Wollack, 1997) was computed for all within-center examinee pairs across all the test centers (5640 of them). The ω index was statistically significant at the 1% level for 367 pairs of examinees among the 5640 pairs, that is, for 6.5% of all pairs—this percentage indicates an unusually large extent of answer-copying present for the data. The percentage of statistically significant values of ω was 27.5% at the 1% significance level in test center TC1. Among the 48 examinees flagged by the credentialing organization, 15 examinees feature in at least one of the 367 pairs with statistically significant values of ω ; interestingly, this set of 15 examinees includes all six individuals belonging to test center TC1 who were flagged by the credentialing organization. For a pair of examinees from test center #2305 both of whom were flagged by the credentialing organization, the number of matching incorrect answer options is 17 (that is the third quartile of the corresponding variable over the within-center examinee pairs) and the p-value for the ω index is 0.00002. Thus, the application of the ω index seems to produce useful information in detecting test fraud in the form of similarly answered items for examinees at the same test center.

Example 2: analysis of answer changes

The data set consisted of the scores of a random sample of 2710 high-school students on 46 dichotomous items on a computerized end-of-course assessment for a particular subject area from a US state. The test is high-stakes for both the students and teachers. The students in the sample were from about 30 schools. The item parameters for the three-parameter logistic model (3PLM) were estimated for the data using marginal maximum likelihood estimation—the 3PLM showed adequate item fit for the data. The median number of answer changes among the students in the sample was 1 (that represents about 2% of all items), which is in agreement with the prevalence of erasures reported by Primoli et al. (2011).

Multiple strong sources of evidence pointed to test fraud at one particular high school, henceforth denoted as school HS_1 . The data set included 205 students from School HS_1 among whom 159 made at least one answer change. The median number of answer changes among the 205 students of School HS_1 was 4, which is four times that in the full sample. The (frequentist) L-index (Sinharay et al., 2017), which quantifies the difference between the estimated ability on the items with answer changes and items with no answer changes and approximately follows a standard normal distribution under no test fraud, was computed for each examinee. The EDI for each examinee was computed using a continuity correction of 0.5 as in Wollack et al. (2015). The weighted maximum likelihood estimate (WLE; Warm, 1989) was used as the estimate of the examinee ability.

Table 2 shows the percentages of p-values that were statistically significant at the 1% level for the two approaches among examinees who made at least one answer change on the assessment. For the L-index and the EDI, a value larger than 2.33 (that is the 99th percentile of the standard normal distribution) of the statistic was considered statistically significant. The first row of numbers in the table provide the percentages among the examinees who were not in School HS_1 (that is, in any school other than HS_1) and made at least one answer change. The second row of numbers provide the percentages among the 159 examinees in School HS_1 who made at least one answer change; thus, for example, the percentage of 12.6 for the L-index in the second row indicates that among the 159 examinees in School HS_1 who made at least one answer change, the index was statistically significant at the 1% level, that is, larger than 2.33, for 20 examinees (note that $\frac{100 \times 20}{159} \approx 12.6$).

The percentage of significant values for either examinee group is larger for the L-index than for the EDI, which is consistent with the finding of Sinharay et al. (2017) that the latter statistic is conservative. One important finding in Table 2 is that the percent significant for each approach is considerably larger among students from school HS_1 than among other students. For example, while the L-index was significant for only 1.4% examinees among other schools, the index was significant for about 12.6% of the students in School HS_1 . This result is favorable to the approaches in the sense that they seem to work as intended in practice by flagging many students from a school (HS_1) that appears suspicious from several sources of evidence.

Table 2 The percentages of examinees with at least one answer change and statistically significant p-values for the L-index and EDI.

Examinees	L-index	EDI
Not in HS_1	1.4	0.7
In HS_1	12.6	7.5

Example 3: person-fit analysis

The data set from the international credentialing examination, which was considered in Example 1, was used to perform person-fit analysis. Two parametric person-fit statistics— ζ_2 (Tatsuoka, 1984) and I_z^* (Snijders, 2001)—were used in the analysis.

The Rasch model is operationally used in the credentialing test; however, the two-parameter logistic model (2PLM) was found to fit the data better than the Rasch model—therefore the 2PLM was used in the analysis. The item parameters under the 2PLM were estimated from the data set and were used to compute the person-fit statistics. The weighted maximum likelihood estimate (WLE; Warm, 1989) was used as the estimate of the examinee ability. For ζ_2 and I_z^* , the critical values at the 1% significance level were 2.33 and -2.33, respectively, which are the 99th and first percentiles of the standard normal distribution.

Table 3 shows the percentages of examinees for which the p-values were statistically significant at the 1% level for the two person-fit statistics. The first row of numbers provides the percentages among the examinees that were not flagged by the credentialing organization. The second row of numbers provides the percentages among the 48 examinees who were flagged by the credentialing organization. Thus, for example, the percentage of 8.3 for I_z^* in the second row indicates that among the 48 examinees flagged by the credentialing organization, I_z^* was statistically significant at the 1% level, that is, smaller than -2.33, for four examinees (note that $4/48 = 0.083$).

Table 3 shows that the ζ_2 statistic led to fewer significant values among non-flagged examinees and more significant values among flagged examinees compared to I_z^* . The table also shows that the percent significant for each person-fit statistic is much larger among the examinees flagged by the credentialing organization compared to among non-flagged examinees—this result provides some evidence that the person-fit statistics provide useful information by being significant at a larger rate among the examinees who are truly aberrant for all practical purposes.

To obtain further insight regarding person fit, the 170 items in the data set were divided into 10 groups using their proportion correct values. Thus, the 17 items with 10 smallest proportion correct values formed item group 1, the 17 items with next 10 smallest proportion correct values formed item group 2, ..., the 17 items with the 10 largest proportion correct values formed item group 10. For each examinee, the proportion correct on the 10 item groups were computed. One would expect the proportion corrects on item groups 1 to 10 to be roughly in an increasing order for each examinee. The four panels in Fig. 1 show, for each of four examinees, the proportion corrects on the 10 groups of items. A loess-smoothed curve (drawn using the scatter smooth function in R; R Core Team, 2021) is also shown in each panel. The range of the vertical axis is the same for all four examinees. The values of ζ_2 and I_z^* were significant for Examinees 1–3 while they were not significant for Examinee 4. While the proportion corrects mostly are in increasing order for Examinee 4, they are not so for Examinees 1–3 (for Examinee 3, the proportion corrects are mostly increasing except a sharp drop for item group 6)—it is then quite natural that ζ_2 and I_z^* indicate misfit for the latter examinees.

Example 4: use of score differencing to detect item preknowledge

The credentialing data set described in Examples 1 and 3 can be used to detect item preknowledge because 61 items were identified as compromised by the credentialing organization. A frequentist and a Bayesian approach were used to detect item preknowledge. The 2PLM was used in all the analyses.

The frequentist approach comprised the use of the signed likelihood ratio statistic L_s (Sinharay, 2017) that quantifies the difference between the estimated ability on the compromised items and non-compromised items—substantial item preknowledge would cause the statistic to be a large positive number. The large-sample distribution of L_s is the standard normal distribution under the null hypothesis of no item preknowledge (Sinharay, 2017).

The Bayesian approach comprised the use of the predictive p-value (Wang et al., 2017) of the raw score on the compromised items. A Markov chain Monte Carlo algorithm was used to simulate draws from the posterior distribution of the examinee ability given the scores on the non-compromised items, posterior predictive data sets were generated using the draws from the algorithm, and then predictive p-values were computed for each examinee using the raw score on the compromised items as the test statistic. A standard normal prior distribution was used on the examinee ability.

Table 4 shows the percentages of examinees for which the p-values were statistically significant at the 1% level for the frequentist and Bayesian approaches. The two rows of numbers provide the percentages among the examinees who were not flagged and flagged, respectively, by the credentialing organization. While the two percentages are similar in each row of

Table 3 The percentages of examinees with statistically significant p-values for the person-fit statistics for the credentialing data.

Examinees	I_z^*	ζ_2
Not flagged	2.2	1.6
Flagged	8.3	10.4

Fig. 1 Average proportion corrects on sorted item groups (and smooth curves) for four examinees.

Table 4 The percentages of examinees with significant p-values in the analysis to detect item preknowledge for the credentialing data.

Examinees	Frequentist	Bayesian
Not flagged	3.1	3.8
Flagged	18.8	21.2

the table, the Bayesian approach leads to slightly larger numbers of significant p-values for both group of examinees. The table also shows that the percent significant for each approach is much larger among the examinees flagged by the credentialing organization compared to among non-flagged examinees—this result provides some evidence that the approaches provide useful information by being significant at a larger rate among the examinees who truly were involved in test fraud for all practical purposes.

Fig. 2 shows the kernel-density estimates (computed and plotted using the function “density” in the R software [R Core Team \(2021\)](#)) of the distributions of the proportion corrects on the compromised and non-compromised items of the examinees who had statistically significant p-values at the 1% level for both the frequentist and Bayesian approaches and the remaining examinees. These two groups of examinees are referred to as “detected” and “non-detected,” respectively, in the legend of the figure. The figure indicates that the detected examinees performed much better on the compromised items than on the non-compromised items while the non-detected examinees performed slightly better on the non-compromised items than on the compromised items. Also, the performance of the detected examinees is much better than the non-detected examinees on the compromised items.

Fig. 2 Proportion corrects for the detected and non-detected examinees on the compromised and non-compromised items.

Conclusions and recommendations

A brief review of the five main statistical methods for detecting test fraud identified by [Wollack and Schoenig \(2018\)](#) is provided. For each of the five areas, some popular approaches are briefly described. Four real data examples are used to demonstrate the application of some of these approaches.

One feature of the real data examples is that the statistics (for detecting test fraud) are significant for only a fraction of the known cheaters. For example, for the data set from the international credentialing examination, 48 examinees were known to have been involved in test fraud and yet, only 15 (that is, about 31%) of them were associated with a statistically significant value of the ω index in the first example, about 8% of them had a significant value of the I_z^* statistic in the third example, and about 19% of them had a significant value of the L-index in the fourth example. There are two primary reasons of this apparent lack of effectiveness of the statistics. First, while it is known that 48 examinees were involved in test fraud, information on which examinee was involved in what type of fraud was unavailable; if such information were available, the statistics would most likely have been more effective. Second, almost all statistics for detecting test fraud suffer from modest power (e.g., [Ferrara, 2017](#)). Together with a small percentage of cheaters in a typical sample of examinees, the low power often leads to the number of false positives larger than that of true positives in an examinee sample (e.g., [Skorupski and Wainer, 2017](#)). The lack of high power often arises from the lack of data. For example, in the second example, erasure analysis for each examinee was based on 46 dichotomous item responses—larger number of items on the test would have led to considerably larger power. However, the fact that these statistics are significant at a substantially larger rate among the known cheaters than among the rest of the examinees provides evidence that these statistics are somewhat useful.

As the above review shows, there exist several approaches for detecting test fraud. However, there remain several unanswered questions on how these approaches should be used in practice. For example, how many approaches should be used and which ones for a specific data set? [Wollack and Cizek \(2017b, p. 397\)](#) warned against the use of multiple conceptually similar methods and commented that evidence of cheating from distinctly different indices can be quite compelling. They also recommended controlling for false positives in the context of test fraud where several statistical tests are typically performed on many examinees; one way to limit the number of false positives is to choose a critical value that adjusts for multiple comparisons by controlling the family-wise error rate (using, for example, a Bonferroni correction) or controlling the false discovery rate (using the procedure of [Benjamini and Hochberg, 1995](#)). [Buss and Novick \(1980\)](#) asserted that “statistical methods of detection should generally not be the sole basis for a judgment that an examinee cheated (or that an examinees scores are sufficiently questionable to justify non-reporting) in the absence of corroboration from other types of evidence.” Other researchers such as [Holland \(1996\)](#), [Hanson et al. \(1987\)](#) and [Tendeiro and Meijer \(2014\)](#) made similar recommendations. However, test-security experts such as [Wollack and Cizek \(2017a, p. 200\)](#) have recently presented the viewpoint that statistical evidence based on even a single statistic may constitute conclusive proof of cheating provided the statistic has been properly vetted and accepted by the research community and the degree of aberrance is clearly extreme.

Background on rater effects in constructed response scores

Tasks that measure complex skills and constructs such as critical thinking, collaboration, or technological literacy, typically cannot be scored by a simple machine like selected-response items—they require human raters to score them. Human raters are trained and instructed to follow a scoring rubric or scoring guide, however many factors may lead to raters' deviation from the rubrics, thereby yielding scores on tasks that do not solely reflect the test takers' knowledge, skills, and abilities. Instead, scores and their corresponding consequences such as decisions about individuals and groups, are impacted by rater biases and errors. These errors contribute to the scores' construct irrelevant variance which in turn degrades the test takers' scores and decisions made about them. Rater effects are patterns or systematic variance in scores resulting from common rater errors. Part of upholding professional standards for testing is explicitly addressing the issue of rater errors in order to minimize them (e.g., see Section 2.3.3 of [International Test Commission, 2012](#); [American Educational Research Association, the American Psychological Association and the National Council on Measurement in Education, 2014](#)).

In order to reduce these errors from occurring in the first place, the best practice is to take measures during the test and item development process to generate items with clearly defined rubrics that will minimize construct irrelevant variance ([ETS, 2021](#)). In addition, rater selection and training should also be carefully performed, with consideration of the types of raters and the most effective training for accurate scoring. Unfortunately, despite these countermeasures, raters still make errors, as they are human.

The literature on rater effects and the impacts of them is vast and well-developed (see [Saal et al., 1980](#); [Wolfe and McVay, 2012](#)). In general, estimates of rater effects can be used in many ways. First, estimates can be used to statistically adjust scores by using modeling techniques that will account for rater effects. There is evidence to show that ignoring rater effects, especially in certain assessment situations, can have a detrimental impact on scores thereby reducing their reliability and validity of their interpretation and uses ([Casabianca and Wolfe, 2017](#); [Guo, 2014](#); [Hombo et al., 2001](#)). It is also possible that rater effects do not have a detrimental impact as they may “cancel each other out” in certain rating designs ([Hombo et al., 2001](#)). Second, rater effects estimates can be used to monitor raters and/or give them feedback to improve their use of the score scale. This chapter describes the common rater effects, metrics and modeling techniques that can be used to detect rater effects, and some factors in model selection.

Common rater metrics and rater effects

A major focus of quality control monitoring in most CR scoring systems is the estimation of interrater reliability or consistency. The ability for multiple raters to use the same scoring criteria and yield consistent scores on the same responses shows the extent to which training procedures, the rubric, and other scoring materials provide the necessary foundation for raters to derive the same evaluation of test taker responses. Low levels of rater consistency reveal weaknesses in this foundation. However, just because interrater reliability is high, does not necessarily mean that the scores they yield are technically accurate. Ratets can be in agreement on incorrect scoring decisions. They may have similarly misunderstood the rubric, for example.

For this reason, another traditional focus of quality control monitoring is on rater accuracy (or inaccuracy). The notion of rater accuracy is complex, or “multi-componential” as per [Cronbach \(1955\)](#). He decomposed accuracy into four parts: (i) elevation, or overall accuracy, (ii) differential elevation, or discrimination among test takers, (iii) stereotype accuracy, or discrimination among traits, and (4) differential accuracy, or discrimination among test takers within traits. Different measures of rater accuracy that are linked to specific components may not be correlated. The more common, or traditional, measures of rater inaccuracy capture the extent to which a rater assigns scores inconsistent with the true score (or approximations of the true score), which is the test taker’s score if there was no measurement error. Rater accuracy measures may be criterion-referenced, when the rater is compared to a score assigned by an expert, or norm-referenced, when the rater is compared to a score based on a consensus from many raters scoring the response. It is very common in practice to use criterion-referenced measures of rater accuracy to monitor raters. To do this, a set of responses each are scored by an expert to produce a set of “validity responses.” The validity responses are then embedded into the queue of responses scored by each rater and the raters’ scores on the validity responses are compared to the experts’ scores to evaluate the raters’ accuracy. An example of a norm-referenced approach is the correlation between a rater’s scores and the average score across raters, denoted by $(r_{x, \bar{x}})$.

Rater effects manifest as systematic variance in scores, however, rater inaccuracy is often discussed as a rater effect even though it is not necessarily systematic. As Wolfe puts it, rater inaccuracy is the extent to which “raters assign scores that deviate from true scores in a random, unpredictable manner” (2014, p. 8). Rater accuracy can be captured with different metrics depending on the data available and these different metrics may be capturing different components of rater accuracy. Despite established complexities in measuring components of rater (in)accuracy, it is mostly basic agreement statistics that are used to measure it. These measures include the percent exact agreement, correlations, kappa, or quadratically weighted kappa (QWK) (see [Burry-Stock, 1996](#)) for an accessible description of how these measures are computed and interpreted).

Taken together, these traditional measures of interrater reliability and rater accuracy can provide a picture of how consistently raters use the scoring rubric and score scale and the accuracy of individual raters and the rater pool overall. However, other measures may be able to better provide more detailed feedback to raters to address specific issues with their use of the rubric. Rater effects are patterns in a rater’s scoring behavior and are not isolated when using these traditional metrics. Some common rater effects include:

- **Severity/Leniency:** One of the most commonly discussed rater effects is the error of rater severity. Severity occurs when a rater tends to score harshly, or lower than they should. Leniency occurs when a rater assigns a higher score than they should. This is sometimes referred to as rater bias, as the error can be in either direction. Differential severity/leniency errors occur when a rater is severe/lenient in their scoring behavior with a particular subgroup, but on average, does not exhibit that behavior with other subgroups.
- **Centrality/Extremity:** While not the most commonly discussed, centrality is a rater error that may be the most common error made in practice. For any number of reasons, a rater may rely heavily on the middle of the score scale. This scoring behavior is akin to “playing it safe” whereas the opposite use of the score scale leads to extremity. Extreme raters essentially use the score scale as a dichotomy, giving either the highest or lowest possible score.
- **Restriction of Range:** Restriction of range occurs when a rater clusters his or her ratings around an area of the score scale, not necessarily the middle. It has also been defined as the “extent to which obtained ratings discriminate among different ratees in terms of their respective performance levels” ([Saal et al., 1980](#), p. 417). There has been some confusion in the literature about how to distinguish centrality from restriction of range. Centrality can be thought of as a special case of restriction of range in which the cluster of ratings is in the middle of the score scale. Restriction of range may occur if a rater is severe, lenient, and/or central in their scoring.
- **Halo Effects:** Halo effects manifest as correlated errors in the ratings which occur when a rater assigns multiple ratings to a test taker’s response(s), whether they are ratings for responses to multiple prompts, or multiple ratings of the same response using different domains. The errors are correlated because information from one response affects the rater’s rating of other responses. For example, if a rater is assigned to rate three responses from the same test taker and the rater is more lenient on rating the second and third responses as a result of a positive feature they observed on the first response.

Importantly, when raters are scoring over a duration of time, they may drift in the scoring behavior ([Casabianca et al., 2015](#); [Condon and McQueen, 2000](#); [Leckie and Baird, 2011](#); [Wilson and Case, 2000](#)). This is not a constant rater effect as the other rater effects described above, but drift is a contextual concern and rater monitoring is an important step to maintain the quality of scores.

For a thorough treatment of rater effects and how they manifest in ratings, refer to [Wolfe and McVay \(2012\)](#), [Myford and Wolfe \(2003\)](#), and/or [Wolfe \(2014\)](#).

Rater effects modeling

Observed score rater effects indices

The term “observed score” rater effects indices refers to metrics that quantify rater effects based on the raw scores or ratings that were observed or collected. This is converse to model-based indices, such as the item response theory (IRT) metrics later discussed in the section on [IRT model-based rater effects indices](#).

Performing an analysis of rater score distributions can reveal much about how a rater uses the score scale. For example, a rater who assigns 75% 5s on a 1–5 scale may be labeled as a lenient rater. This is an analysis that is easy to understand and explain, but only feasible for a small rater pool and relies on assumptions such as a random sample of test takers and also a random assignment of raters to responses. When there is a large number of raters, it is more convenient to rely on basic summary statistics that have been shown to correlate with specific rater behaviors (Wolfe, 2014). This also assumes random assignment of responses and large numbers of responses used in the calculation. Rater severity is captured by the mean of individual rater's ratings ($\bar{X}_r$)—raters with means higher than the overall mean tend to be lenient, and raters with means lower than the overall average tend to be severe. Rater centrality can be captured by the standard deviation (SD) of individual rater's ratings (SD_r). Raters with relatively large SDs might be extreme in their scoring and use the ends of the score scale. Raters with relatively small SDs might be central in their scoring and use the middle categories. Rater SDs can also capture range restriction in general, and thus it is also important to consider the distance of the rater's mean to the middle of the score scale. As mentioned above, observed score metrics for rater inaccuracy can include agreement measures based on a criterion- or norm-referenced approach.

IRT model-based rater effects indices

There are limitations to the information observed score metrics can provide because of the differences in the other facets of the measurement process that go unadjusted for in basic summary statistics. A statistical model can make adjustments for item effects, person effects, and more, if necessary. There are many modeling frameworks within which to examine rater errors. Generalizability theory, in particular, is an approach to decomposing the variance in scores attributable to various facets (Brennan, 1992). However, another natural modeling framework to address this in the constructed-response scoring scenario is IRT (Lord, 1980).

IRT models are probabilistic models used to scale item response data. Readers new to IRT are encouraged to learn more in the chapter on IRT in this Encyclopedia and in other introductory sources (see the ITEMS module: Penfield, 2014). In a common set of IRT models called the 2-parameter logistic IRT models, items are characterized by a set of parameters that describe item difficulty and item discrimination, or an item's ability to distinguish test takers (Lord, 1980). An even simpler model is the Rasch model or the 1-parameter logistic IRT model, which only includes the item difficulty parameters (Rasch, 1960). In all IRT model formulations, test takers are characterized by a latent ability parameter θ_i , which reflects their standing on the construct being measured by the test on a scale ranging from $-\infty$ to $+\infty$ (commonly specified as a standard normal distribution, centered at 0 with standard deviation of 1.0). For polytomous items, scored on a discrete scale with more than 2 points, there are specific IRT models used to appropriately capture response patterns and determine the locations of the boundaries for the score levels along the scale of the underlying latent ability. For example, the generalized partial credit model (GPCM; Muraki, 1992) given by

$$\pi_{ijx} = \frac{\exp \left[\sum_{k=1}^x \alpha_j (\theta_i - \beta_j - \gamma_{jk}) \right]}{\sum_{c=0}^{m_j} \exp \left[\sum_{k=1}^c \alpha_j (\theta_i - \beta_j - \gamma_{jk}) \right]}, x = 0, 1, \dots, m_j \quad (1)$$

expresses the probability π_{ijx} that a test taker i ($i = 1, \dots, N$) will achieve a score x on their response as a function of four types of parameters: latent ability (θ_i), item discrimination (α_j), item location/difficulty (β_j), and the item category threshold (γ_{jk}), where k refers to the threshold between score category x and the adjacent lower category $x-1$, and m_j refers to the number of possible categories for item j . Note that Model 1 implies that:

$$\ln \left[\frac{\pi_{ijk}}{\pi_{ij(k-1)}} \right] = \theta_i - \beta_j - \gamma_{jk}. \text{ The partial credit model (PCM; Masters, 1982) is a polytomous Rasch model and is a special case of the}$$

GPCM in which the item discrimination is equal to 1.0 for all items. IRT rater models are based on these same principles, but they are used to measure and describe rater behaviors.

Models with rater parameters

Models incorporating rater parameters are perhaps the most widely used when the analysis goal is to account for rater effects when scoring test takers. The multi-faceted Rasch model (MFRM; Linacre, 1989) is probably the most popular because of its relative accessibility and ease of interpretation. The traditional Rasch model as discussed earlier, includes a difficulty parameter for the item. The MFRM is an expanded version that also includes parameters for other facets, including raters. Note that the MFRM is recognized as a special case of Fischer's linear logistic trait model (1973). The MFRM based on the PCM (Masters, 1982) is given by

$$\ln \left[\frac{\pi_{ijrk}}{\pi_{ijr(k-1)}} \right] = \theta_i - \beta_j - \gamma_{jk} - \phi_r \quad (2)$$

where θ_i is the latent trait for test taker i , β_j is the location or difficulty for item j , γ_{jk} is the k th threshold for item j , and ϕ_r is the severity for rater r . Both β_j and ϕ_r are quantities on the logit scale (centered at 0) that affect the probability of observing a score

category. Specifically, when $\phi_r > 0$ the probability will be lower as the quantity is subtracted. This means that the rater tends to score low relative to the average rater ($\bar{\phi} = 0$) and so the rater is (relatively) severe. The opposite is true when $\phi_r < 0$; in this case, the rater is lenient relative to the average rater. Much research on rater effects and IRT modeling is based on the MFRM and how it can be used to detect rater effects (Linacre, 1989; Myford and Wolfe, 2003, 2004). Expanding the MFRM is relatively straightforward and therefore it offers a lot of flexibility to those with complex designs and needs—there are numerous other variants of the MFRM that capture more than just rater severity (Eckes, 2009; Myford and Wolfe, 2003).

The model in (2) is sometimes referred to as an item-related three-facet PCM since the thresholds term γ_{jk} is allowed to vary by item j (Eckes, 2009). A simpler version models one set of thresholds γ_k for all items. Yet another variant is the rater-related three-facet PCM which models γ_{rk} , or rater-specific thresholds representing the difficulty of score category k relative to rater r , removing the item-specific thresholds. In this case the rating scale is allowed to vary by rater, but applies to all items. The SD of these rater-specific thresholds is a measure of rater centrality in that when most of the ratings are in the center of the score scale, the rater will have a wider dispersion of thresholds yielding a large SD. In the item- and rater-related three-facet PCM, γ_{jrk} measures the rating scale for each rater and item. All of these variants are based on facets as main effects, but there are variants that utilize interaction effects to model other aspects of scoring, including interactions between raters and test takers (Eckes, 2009; Myford and Wolfe, 2003). Further, though the MFRM does not explicitly capture rater accuracy with a parameter, other measures are used to approximate it (Linacre, 2004; Wind and Engelhard, 2012; Wind et al., 2016; Wright and Masters, 1982).

Importantly, the MFRM and its variations treat multiple ratings of the same item response as “pseudoitems” or “virtual items” (Wang et al., 2014) in which rater-item combinations are treated as separate items. IRT models assume that item responses are independent conditional on the latent trait, or they assume *local independence* given the latent trait. However, it is unreasonable to make that assumption in these models since it is unlikely that ratings assigned to the same response will be independent. Treating ratings in this way ignores the dependencies that exist in the ratings of the same responses given by different raters. There are ramifications to this, which are discussed in **Factors in model selection** section.

The class of hierarchical rater models incorporate the hierarchical structure of the data that exists when there are multiple ratings of the same response thereby accounting for the local dependency that the MFRM ignores (DeCarlo et al., 2011; Patz et al., 2002). Depending on the model specification, these may incorporate parameters for rater severity, centrality, and/or intra-rater reliability or consistency, among other rater effects. In the original hierarchical rater model (HRM; Patz et al., 2002), the first level of the hierarchy uses a signal detection approach to model the distribution of ratings given the “ideal” rating which is the rating free of bias or unreliability, the second level models the distribution of a test taker’s ideal ratings given their latent trait θ_i , and the third level models the distribution of the latent trait θ_i .¹ The hierarchical representation of the HRM is given by

$$\begin{aligned} X_{ijr} | \xi_{ij}, \tau_r^2, \phi_r &\sim \text{polytomous signal detection model, } r = 1, \dots, R, \text{ for each } i, j. \\ \xi_{ij} | \theta_i, \beta_j, \gamma_{jk} &\sim \text{GPCM as in (1), } j = 1, \dots, J, \text{ for each } i \\ \theta_i &\sim N(\mu_0, \sigma_0^2), i = 1, \dots, N \end{aligned} \quad (3)$$

Here, θ_i , the latent trait for test taker i ($i = 1, \dots, N$) is normally distributed with mean μ_0 and σ_0^2 . This is a typical IRT specification for the latent trait, and depending on the model constraints, often $\mu_0 = 0$ and $\sigma_0^2 = 1.0$. The ξ_{ij} is the discrete ideal rating for test taker i on item j ($j = 1, \dots, J$) taking on values 1 to m_j , modeled using the GPCM as given in (1) but with the observed score replaced by the ideal ratings, which are latent variables. Finally, X_{ijr} is the observed rating given by rater r for test taker i ’s response to item j . In the original HRM, the signal detection model for rater bias (severity or leniency) ϕ_r and rater variability τ_r^2 is:

$$P[X_{ijr} = k | \xi_{ij} = \xi] \propto \exp \left\{ -\frac{1}{2\tau_r^2} [k - (\xi + \phi_r)]^2 \right\}, \quad (4)$$

where for each set of rating probabilities conditional on $\xi_{ij} = \xi$, the probability that the observed rating equals k is approximately equal to normal density with mean $\xi + \phi_r$ and variance τ_r^2 (Patz et al., 2002). The bias parameter is a continuous measure of bias on the scale of the raw score scale. When $\phi_r > 0$, rater r has positive bias or is lenient, and when $\phi_r < 0$, rater r has negative bias, or is severe. The variability parameter is often analyzed in its reciprocal form as a rater precision parameter, capturing the consistency with which a rater scores around the ideal rating offset by their individual bias or ϕ_r (Casabianca and Wolfe, 2017). The model is typically estimated as a Bayesian model with Markov chain Monte Carlo (MCMC) estimation. The model in (3) assumes prior distributions for unknown parameters including the precision of the latent traits $\omega = 1/\sigma_0^2$, the difficulty parameters β_j and step parameters of the IRT model γ_{jk} , and the rater parameters, $1/\tau^2$ and ϕ . Due to the model’s modularity, the basic HRM as discussed in Patz et al. (2002) has been expanded into a framework of HRMs with various special cases. For example, the signal detection layer of the model can be specified in different ways to incorporate more rater effects and idiosyncratic scoring behaviors than just bias and consistency (DeCarlo et al., 2011). In addition, other levels of the model can be adapted for longitudinal data designs (Casabianca et al., 2017) as well as multidimensional assessments (Nieto and Casabianca, 2019). For more information on full HRM framework, see Casabianca (2021).

Other IRT rater models such as the rater bundle model (RBM; Wilson and Hoskens, 2001) and the model for multiple ratings (MMR; Verhelst and Verstralen, 2001) were introduced around the same time as the HRM to address the same problem,

¹See DeCarlo (2005) for a primer on signal detection theory applied to the ratings context.

and more recently the MFRM was extended to address local dependence among multiple ratings for the same response (Wang et al., 2014).

Models without rater parameters

IRT models *without* rater parameters may be fit to ratings data with different assumptions. First, there may be the case that rater effects are completely ignored and a polytomous IRT model is used to scale the data, ignoring rater differences. This becomes complicated when there are multiple ratings for responses, in which case the multiple ratings may be aggregated somehow (e.g., averaged and then rounded), or the multiple ratings may be included as multiple item responses (or multiple items). Alternatively, IRT models without rater parameters may be used purposefully to analyze rater effects in the single-item context. In this case, in a rater response model, there are N test takers responding to one item, and the model treats raters as items. In this approach the model estimates the traditional item parameters (discrimination, difficulty, and thresholds) but in this context they take on a different interpretation as measures of rater effects. For example, in the rater response GPCM (RR-GPCM), which is an extension of the basic GPCM, the difficulty parameter is a measure of rater severity, the discrimination parameter is a measure of rater accuracy, and the SD of the thresholds is a measure of rater centrality (Stafford et al., 2018; Wolfe and McVay, 2012; Wolfe, 2014).

The RR-GPCM given by

$$\pi_{irx} = \frac{\exp\left[\sum_{k=1}^x \alpha_r(\theta_i - \phi_r - \gamma_{rk})\right]}{\sum_{c=0}^m \exp\left[\sum_{k=1}^c \alpha_r(\theta_i - \phi_r - \gamma_{rk})\right]}, x = 0, 1, \dots, m \quad (5)$$

is the same formulation as in a traditional GPCM in (1) except for the item parameters are now indexed by r instead of j because they are associated with raters. That is, π_{irx} is the probability that a particular rater r ($r = 1, \dots, R$) will assign rating x to test taker i ($i = 1 \dots N$) as a function of test taker location (θ_i), rater accuracy (α_r), rater location (ϕ_r), and the rating scale category threshold (γ_{rk}) of rater r .² Rater accuracy in this model is a norm-referenced indicator describing the rater's ability to discriminate test takers. Fitting this model to one item at a time may not be optimal if there is more than one CR item on the test, but it can be a valuable model to explore if the goal is to analyze and flag aberrant raters.³

Other polytomous IRT models can also be used in a similar fashion (Andersen, 1997; Andrich, 1978; Rasch, 1961; Samejima, 1969). Even dichotomous IRT models may be useful for ratings data (Engelhard, 1996). For example, a Rasch model fit to validity agreement data (agree = 1, disagree = 0) can be useful for capturing rater accuracy, or scaling raters. See Chin et al. (2014) for an example on how this can be applied in practice.

Empirical example: monitoring raters in a teacher licensure performance assessment

Understanding how best to measure teachers and teaching effectiveness with standardized tools has been a focus in recent educational research (Hill et al., 2008; Kane et al., 2013). Assessments for teacher licensure have mostly been focused on content knowledge, however, the *Foundational Assessment of Competencies for Teaching* (FACT) is an online performance assessment for teacher licensure that assesses not only teachers' content knowledge, but teaching skills (Phelps et al., 2020). In this section, FACT pilot study data demonstrate and compare rater effects indices from different modeling approaches.

Summary of the FACT pilot data

The FACT was pilot tested using 57 teacher candidates, each of whom were rated on 14 tasks (7 Math, 7 Reading & Language Arts) by 14 raters. All tasks were scored on a 3-point scale. In total there were 617 scorable performances scored by 3 randomly selected raters resulting in 1851 ratings. In addition to scoring these responses, each rater scored 74 validity responses for purposes of rater evaluation. Scoring accuracy was measured with validity agreement rates (see Table 1). Percent exact agreement ranged across raters from 0.51 to 0.68. Considering the 3-point scale, this level of agreement is suboptimal, however, these data were collected as part of an experimental formative training exercise and not meant to contribute to scores for teachers.

IRT rater model results compared to observed score metrics

An analysis using the MFRM, HRM, and RR-GPCM (as specified in Eqs. (2), (3) and (5)) demonstrates the IRT modeling approach, comparing it to the observed score metrics of rater effects and the accuracy estimates based on validity responses.^{4,5} As specified, all three IRT models provide an estimate of rater severity, the RR-GPCM and HRM provide measures of rater accuracy, and the RR-

²Note the Greek letter used for the item location has changed from (1) to be consistent with the severity parameters of other models.

³Though the GPCM is discussed here, see Masters and Wright (1997) for an example demonstrating the PCM to calibrate raters.

⁴The RR-GPCM was fit to the FACT pilot data using maximum likelihood estimation. The HRM and MFRM were fit to the data using MCMC estimation.

⁵For convenience the RR-GPCM analysis uses the full dataset (ignoring any item differences) since the score characteristics for the 14 items were very similar (Phelps et al., 2020). In practice, it may be beneficial to fit the RR-GPCM for each item to obtain a series of estimates for each rater.

Table 1 Rater agreement rates on validity responses for the FACT pilot data.

Rater	Validity agreement rates		
	Exact	Adjacent	Discrepant
03	0.68	0.32	0.00
11	0.68	0.31	0.01
06	0.66	0.32	0.01
09	0.66	0.32	0.01
12	0.66	0.32	0.01
05	0.62	0.35	0.03
07	0.61	0.39	0.00
13	0.61	0.36	0.03
04	0.59	0.38	0.03
02	0.58	0.41	0.01
08	0.58	0.39	0.03
10	0.57	0.41	0.03
01	0.51	0.43	0.05
14	0.51	0.43	0.05

Note. Raters are sorted descending by exact agreement rate.

GPCM also provides a measure of rater centrality.⁶ These measures may be compared to their observed score counterparts (mean, SD, and the correlation between raters' scores and the average of the triple scores). Table 2 provides the rater effects indices for all models, grouped by rater effect to facilitate comparisons across models.

With respect to severity, low rater mean scores reflect severity while high mean scores reflect leniency. Both the RR-GPCM and MFRM estimates are centered at 0 in this analysis, thus estimates for severe raters will be relatively more positive than other raters, and estimates for lenient raters will fall in the other direction—they will be negative. The HRM's signal detection model puts rater bias on the raw score scale, so the lenient raters will receive positive bias estimates in the HRM and severe raters will have negative bias estimates.

Table 3 provides the correlation matrix for all rater effects indices and Fig. 1 is a scatterplot matrix of the severity estimates, which shows direct linear relationships between all measures. The strongest relationships were between the severity estimates from the HRM and the GPCM ($r = -0.976$) and the HRM and the MFRM ($r = -0.973$). The high correlation between the severity estimates

Table 2 Rater effects indices and flagged raters for the FACT pilot data.

	RR-GPCM—SD (thresholds)	−0.312	0.158	0.346	−0.322	−0.815	1.000				
Rater accuracy	Percent exact agreement	−0.502	0.536	0.623	−0.572	−0.529	0.303	1.000			
	Corr with mean	−0.423	0.593	0.424	−0.464	0.004	−0.379	0.392	1.000		
	RR-GPCM—discrimination	−0.530	0.568	0.474	−0.482	−0.180	−0.172	0.417	0.864	1.000	
	HRM—rater variability	0.500	−0.662	−0.557	0.579	0.329	0.053	−0.517	−0.884	−0.760	1.000

Note: Grayed cells of the correlation matrix highlight correlations between measures of the same rater effect. No significance tests were conducted due to small sample size ($n = 14$).

Measures of Rater Severity – FACT Pilot Data

Scatter Plot Matrix

Fig. 1 Scatterplot matrix of rater severity based on observed rater means (Rater Mean), and the rater effects estimates from the RR-GPCM, the MFRM, and the HRM.

from the MFRM and the HRM indicates that the MFRM's failure to properly model the correlation from multiple ratings of the same response does not drastically impact this index—instead, the impact would be more prominent in the standard errors of the latent trait estimates which would be larger in the HRM (Patz et al., 2002). The rater mean had the strongest correlation with the rater effect from the MFRM ($r = -0.96$) and that is likely because this version of the MFRM accounts for the least rater behavior compared to the other models and therefore it sorts raters more consistently.

Taking a closer look at Rater 12 reveals a low mean score (1.93) and the largest positive MFRM severity estimate (0.27), indicating that Rater 12 rates relatively severely. However, the RR-GPCM and HRM severity estimates are much smaller and do not indicate a tendency to be severe. In terms of leniency, Rater 10 has the highest mean rating (2.35) and the largest negative MFRM severity estimate (-0.58) as well as the most extreme RR-GPCM and HRM estimates. The RR-GPCM and the HRM estimates are

Fig. 2 Scatterplot of rater centrality based on observed rater SDs (x-axis) and the SD of the rater thresholds from the RR-GPCM (y-axis).

not large enough to indicate substantial leniency and this could be because they account for additional factors. For example, the RR-GPCM accounts for rater behavior along the score scale by including thresholds for raters. The HRM accounts for item effects via the GPCM and in addition to severity it also accounts for rater variability/inconsistency. Also note that all of these IRT models have latent traits and thus they account for test taker effects or the quality of the responses, which the observed mean does not. Accounting for differences in the quality of the response via the IRT modeling approach might change the way raters are ranked with respect to rater effects especially if a rater happens to score a disproportionate number of responses from test takers of low (or high) ability.

Fig. 2 plots the rater SDs against the SD of the rater thresholds from the RR-GPCM. These measures were highly negatively correlated ($r = -0.815$). A central rater will have a relatively small observed score SD compared to other raters as they are scoring in the middle of the score scale and not using the extremes. Conversely, a central rater will have a larger SD of thresholds from the RR-GPCM because their outer thresholds are pushed out into the extremes as a result of scoring so heavily in the middle. This in turn yields the negative correlation. While the correlation is high, it is not perfect and there are raters who would be ranked differently with respect to centrality when using these different indices. Much like when measuring severity with different models, the correlation between centrality indices will not be perfect because of the differences in what these models account for. The SD of thresholds from the RR-GPCM are based on model estimates that account for several factors (quality of the response, rater

Measures of Rater Accuracy – FACT Pilot Data

Fig. 3 Scatterplot matrix of rater accuracy based on the percent exact agreement (%Exact) on validity responses, the correlation with a rater's rating and the mean of all raters' ratings (Corr), the discrimination estimate from the RR-GPCM (RR-GPCM), and the rater SD estimate from the HRM (HRM).

severity, discrimination/accuracy, and the scoring behavior along the scale via thresholds). However, both indices are in clear agreement on the one rater at the top left of Fig. 2 (Rater 03) who is exhibiting a persistent tendency to score in the middle of score scale. Almost 60% of the ratings Rater 03 assigned were at score point 2 (the middle) and the rest of their ratings were split evenly between score levels 1 and 3. Restriction of range would also manifest in these indices as not using the full score scale will impact the SD even if the rater is using different points in between the extremes (not necessarily in the middle). However, since the FACT scale only has three score points there is not much room along the scale to have different clusters of ratings (aside from the one that exists for Rater 03).

Fig. 3 plots a series of rater accuracy measures: the percentage of exact agreement on validity responses, the correlation between the rater's rating and the mean rating, the discrimination estimate from the RR-GPCM, and the rater variability (SD) parameter estimate from the HRM which is a measure of intra-rater consistency. The strongest relationships are between the correlation with the mean rating and the HRM estimate, and the correlation and the GPCM discrimination estimate. The HRM estimate is also strongly correlated with the GPCM discrimination estimate ($r = -0.760$)—it is negatively correlated because larger discrimination estimates reflect higher levels of accuracy, but the HRM variability parameter will be smaller when a rater is more consistent or reliable. These strong relationships are expected since they are norm-referenced measures of accuracy. These measures were only moderately correlated with the percent exact agreement on the validity responses.

Identifying aberrant raters

These metrics provide much information about the raters' behavior which might be used to flag raters for remediation and retraining. Some metrics do not have established thresholds for flagging and thus an empirical approach may be applied, such as traditional outlier detection methods. For example, Rater 10 has a mean score that is extreme relative to the other raters, corresponding to a z -score > 2.5 . This is a large z score and depending on the outlier detection rules used, would probably be flagged as an outlier. Another example of an empirical approach is using the 95th percentile of the rater location estimates and using that value as the threshold for flagging severe raters (Stafford et al., 2018). Some metrics have established lower or upper bounds or rule sets used to flag raters. The MFRM's rater location term ϕ_r represents the relative locations of the raters' mean scores. A rater with $|\hat{\phi}_r - \bar{\phi}| > 0.5$ (more than 0.5 logits from the mean of the ϕ distribution, denoted by $\bar{\phi}$) might be flagged as being severe or lenient compared to other raters (Wolfe and McVay, 2012). In the FACT example, $\bar{\phi} = 0$ and therefore only Rater 10 would be flagged since they are the only rater with $|\hat{\phi}_r| > 0.5$. Other approaches are also used including computing Wald statistics to capture statistically significant deviations from the group mean (Wolfe, 2004).

Thresholds have been suggested for the HRM's rater effects indices. For the rater bias/severity estimate ϕ_r , an absolute value of 0.5 or greater is typically considered nonnegligible bias because it reflects the rater's tendency to score consistently 1 point higher or lower (since differences of 0.5 are rounded to a score point) (Patz et al., 2002). A rater SD of around 0.75 or higher has been noted as an indication of significant rater unreliability because it means that the rater is scoring inconsistently with a fairly large SD (Casanova and Wolfe, 2017).

Rater 03 very clearly has a SD lower than the other raters (albeit not that large in the grand scheme of things), and the RR-GPCM based estimate of centrality supports the notion that this rater is exhibiting centrality. A large(r) SD of thresholds is related to a rater's relatively heavier use of the middle categories since this pushes the thresholds farther apart. While this is only a 3-point scale, Rater 03 did use the middle category 60% of the time compared to the overall raters' behavior in which a score of 2 was only used for 47% of the responses. This difference in score distributions is reflected in the indices.

With respect to rater accuracy, both the correlation and the RR-GPCM accuracy estimate might flag Rater 14 as they had lowest values. Applying the outlier detection method mentioned earlier would flag this rater based on the correlation with the mean ($z < -2.5$) but not on the RR-GPCM accuracy estimate. Certainly, the exact agreement rates would lead to flagging Rater 14 and also Rater 01 however, that measure is based on a different set of responses so it may be considered an external criterion to the other indices and not directly comparable.

In summary, from this analysis the following raters may be flagged:

- Rater 10 would be flagged for scoring relatively higher (or leniently) than the other raters, and this would be supported by the MFRM. The RR-GPCM location estimate and the HRM bias estimate did not reach a "flaggable" quantities, which is typically a magnitude of 0.5.
- The RR-GPCM index would flag Rater 14 for a low level of accuracy. The observed score accuracy indices support this finding.
- Rater 03 would be flagged for centrality by both indices.
- Rater 01 might be flagged using the validity response data (51% exact agreement).

It is important to note that flagging raters on validity agreement statistics alone would have missed possible pertinent retraining and remediation for Raters 03 and 10. Feedback to raters based on their relative standing on rater effects indices can be targeted to address those specific issues. Myford and Wolfe (2003) provide strategies to minimize various rater effects via rater feedback and training.

Factors in model selection

All IRT rater models have specific affordances and limitations and may be appropriate in different use cases and contexts. As such, there are several considerations when selecting a model. Perhaps the first is the rating design, which dictates how raters are assigned to responses to be scored, and how many ratings each response receives. There are spiral designs in which raters score responses to a particular subset of items. There are nested designs in which raters score all responses per a test taker. In a random assignment, often used in online scoring systems for large-scale assessments, raters may score all or any subset of items and not necessarily the same test taker. The rating design is directly related to how the data (test taker responses and raters) are linked to each other,

or the extent to which there is “connectedness” (Engelhard, 1997; Schumacker, 1999). When there is insufficient connectedness of the data, the ability to estimate model parameters may be limited because information about raters and test takers cannot be separated or identified (Stafford et al., 2018; Wind and Jones, 2018).

Independent of the rating design, responses may be scored by multiple raters, or a small subset may be double-scored for the purposes of reliability estimation. How these multiple ratings are treated in the IRT model is naturally a defining factor for model selection. In the IRT context, ignoring the dependencies from multiple raters scoring the same response leads to an accumulation of information which in turn leads to falsely low latent trait standard errors (Mariano, 2002). Users should take caution about the models they choose in this scoring context. In some cases, the user may prefer to consider each rater’s evaluation of the response to be separate information (Linacre, 2003). However, typically when a rater is trained to score according to a rubric, the expectation is that raters should be similar in their evaluation as they are serving as “scoring machines” and their individual views on the response are not valued or considered as separate information. The importance of the rater model in this case is to account for ratings that are not consistent with the rubric or not assigned by raters who are equally good at using the rubric. Ratings should cluster around what is an appropriate value for the response.

Importantly, these models capture different rater effects. Most, if not all, IRT rater models will capture rater severity, but some do not capture centrality and/or accuracy, at least not directly with model parameters. It may be obvious to select the model that captures the most rater behavior or the most rater effects, however, there are several factors to consider which may lead to selecting a simpler model. The relatively more complex models offering more rater effects estimates may not be necessary. Complex models can be difficult to estimate and/or interpret, so it is important to apply them when appropriate and necessary. A preliminary check of observed score rater effects indices may suggest that a specific subset of rater effects must be captured by the IRT model and maybe others are less important. In addition, depending on the rater design, it may be especially important to capture specific rater effects such as halo effects. These types of considerations and determinations should be made a priori.

Another important factor is to understand the goals of the analysis. Is the goal to score test takers? Is the goal to monitor raters and provide feedback? Is the goal to do both? All the IRT rater models discussed here will provide estimates of the latent trait, however, the RR-(G)PCM will do this based on only one item (and multiple raters). This may not be the best way to scale test takers, and so when there is another scoring approach in place for computing scores, there may be a preference to apply this model in the context of rater monitoring only. If scoring is the main goal, using the HRM may be preferable to a model such as the MFRM, which will ignore the dependencies as discussed above.

Finally, a persistent limiting factor in the application of IRT models is sample size. IRT model estimation tends to require somewhat large samples to yield trustworthy estimates. In the event that the dataset is too small, it is advised to use the simpler models such as the MFRM and observed score statistics. Other more complex models such as the HRM may not be feasible due to the number of estimated parameters.

Summary

With the reliance on open-ended tasks and performance assessments and human raters to score these assessments, it is imperative to minimize construct irrelevant variance wherever possible. This chapter addressed different methods for modeling rater effects and flagging raters for aberrant behavior. While most rudimentary scoring systems may use basic agreement measures to compare raters’ scores to other raters’ scores or consensus scores, rater effects indices, both observed score metrics and IRT-based metrics, can provide more diagnostic information with which to provide feedback to raters. Augmenting existing scoring systems with this type of information can increase opportunities for raters to reduce their errors with targeted training. Certainly, creating a scoring system for a new assessment permits the use of the IRT framework from the very start. However, if there are logistical barriers to implementing some of these methods, it is clear that even examining simple observed score statistics can be very insightful.

Rater effects indices can be used in various ways including tracking raters and providing feedback to raters. Ideally future work will be able to connect established thresholds and subsequent decisions to improvements in the validity, reliability, and fairness in test scores and uses. However, overall there is a consensus that the quality control of constructed-response scores and the monitoring of raters is vital to maintaining efficient and effective scoring systems, and some well-defended plan should be in place to ensure the optimal conditions are in place. The interested reader is encouraged to further study the psychometric literature which contains an abundance of works on rater-mediated assessments and rater effects modeling.

Although many process variables recorded from computer-based educational assessments can nowadays be studied (e.g., Provasnik, 2021), response time, generally defined as the time it takes to respond to a test item, remains popular because it can be used for several purposes, is relatively easy to collect, and is typically available for all items. Consequently, the modeling of response times, often alongside item responses, has become an important research topic in educational assessment. For example, response times are studied in a variety of contexts, ranging from group-score assessments such as PISA (Kerzabi et al., 2020) to high-stakes college admission tests (van Rijn et al., 2021). In this entry, we aim to provide a brief review of modeling aspects of item responses and response times in the context of educational assessments.

Response times are often modeled (often under slightly different names such as “reaction time” and “duration”) in scientific fields such as psychology (Luce, 1986) and survival analysis (Cox and Oakes, 1984). However, it is not always easy to transfer concepts across fields in a meaningful way. For example, the speed-accuracy tradeoff often studied in psychological reaction-time experiments is usually observed within persons across time-limit conditions (Goldhammer, 2015), a situation not often encountered in educational assessment. Alternatively, the concept of hazard, the risk of an item not “surviving” the student’s solution process per time unit, may not be that useful in our context. Furthermore, even within the field of educational assessment, the analysis and modeling of item response times may require different approaches. That is, the response type and response time of multiple-choice items and that of extended constructed-response items can be qualitatively and quantitatively different.

Analyses of response times in educational assessment can serve a variety of purposes that can be roughly be divided into two types: (1) enhancing data quality and security, and (2) improving reliability and validity of the test scores. Response-time analyses of the first type can involve basic data-quality checks such as computation of the time test takers spend on the assessment relative to the allotted testing time (Schnipke, 1995) and sophisticated analyses such as detection of cheating behaviors using response times (van der Linden, 2009a; Sinharay, 2020; Sinharay and Johnson, 2019). Response-time analyses of the second type can, for instance, pertain to enhancing measurement precision beyond response accuracy (Bolsinova and Tijmstra, 2018) and evaluating construct-irrelevant factors such as disengagement (Wise, 2019).

Some caution in modeling response times is needed too. For example, Pohl et al. (2021) argue that response-time differences related to proficiency can be confounded with response-time differences related to test-taking behaviors (e.g., working speed). Therefore, there is a need to disentangle these two types in order to enhance test score interpretations (Kane, 2013) and fairness (Dorans and Cook, 2016). Furthermore, response times, and process data in general, may not always be comparable between test takers, for example, if testing accommodations were made available for test takers with disabilities or health-related needs.

Before discussing statistical modeling of response times, it is important to determine what the role of response times is with respect to the outcomes of the educational assessment. By outcomes, we mean results such as the final scores given to individual test takers in an admissions test and the group statistics reported in educational surveys such as PISA. A distinction can be made between levels of importance of response times with respect to the outcomes of an educational assessment (Bergner and von Davier, 2019). Response times can be considered *collateral* to the outcome when they are either irrelevant to the outcome, auxiliary to the outcome, or only important in understanding the outcome. Response times can be considered *essential* to the outcome when they are used in a scoring rubric or in the statistical model that produces the outcome. Consider, for example, the historical distinction between speed and power tests (Gulliksen, 1950). On a speed test, several easy items are to be answered as quickly as possible so that response times are essential to the outcome. In contrast, on a power test, items with a wide range of difficulty are to be answered correctly so that response times are typically collateral to the outcome. Given that most educational assessments are intended to be power tests and time limits are generally imposed for practical reasons, it is important to ask the question what the role of response times should be. This should not only be clear to the test developer, but also to the test taker.

Three additional, conceptual issues pertaining to response times are relevant in the context of educational assessment (van der Linden, 2009b). The first issue concerns the representation of response times as random variables. That is, response times are treated

as realizations of random variables so that methods from mathematical statistics can be used for making inferences (Luce, 1986). The second issue pertains to distinguishing notions of labor intensity to describe items and speed to describe test takers (van Breukelen, 1997). In certain response-time models (e.g., the log-normal model, see the section on separate models for response times), this is done in a similar fashion as the distinction between item difficulty and test-taker ability in case of item responses. Third, conditional independence assumptions such as the independence of response times conditional on latent speed play an important role in response-time modeling. The exemplified assumption is akin to the assumption of conditional (or “local”) independence in item response theory (IRT) models where item responses are independent conditional on latent ability. However, conditional independence assumptions cannot be automatically translated from IRT models to response-time models. For example, between-item dependencies can arise for response times when there is a total test time limit. That is, test takers can spend their time only once, and sequential dependencies between response times can occur if, for instance, test takers spend more time in the first half than in the second half of the assessment. If the time limit is too strict to allow all test takers to see all items, the test is considered speeded, which can lead to methodological and validity issues in the scoring of examinees (Lu and Sireci, 2007). Furthermore, in joint models for item responses and response times, modeling assumptions need to be specified to deal with within-item dependencies between item response and response time. For example, when the difference in mean response time for incorrect and correct item responses varies substantially across items, and this difference is both positive and negative, a flexible model would be needed.

We begin with a section on defining and measuring response times. This is followed by an overview of response-time modeling approaches, supplemented by estimation and model fit. An example of response-time modeling is discussed in some detail. The entry ends with a brief discussion and some suggestions for further reading.

Measuring item response times

Although it is sometimes thought that response times have only become available with the start of computer-based testing (CBT), item-level response times have been collected with paper-based testing as well. For example, Blommers and Lindquist (1944) measured response times by displaying consecutive numbers at 10 s intervals during test administration and asking test takers to record the number before and after each item. Obviously, CBT has simplified the recording of response time, but, in practice, many design features of the educational assessment can impact response time. Before response time can be defined, it needs to be clear on exactly what response it is to be captured, and which design features can impact the recording of response time. We discuss the issue of defining response time by referring to the IMS question and test interoperability (QTI) specification. This is a standard for the digital representation of test content and results developed by the IMS Global Learning Consortium.¹

In CBT, response time can typically be defined as the time difference between two events in the process data log of a test administration. In the QTI specification, “A duration value specifies a distance (in time) between two time points. In other words, a time period as defined by [ISO 8601], but represented as a single float that records time in seconds. Durations may have a fractional part.”² The key issue in defining response time lies in determining which two events are to be used. Furthermore, in the QTI specification, an item session is defined as “the accumulation of all the attempts at a particular instance of an item made by a candidate.” Although a test taker visiting an item multiple times is more or less captured in this definition, it is not explicit. That is, the extent to which test takers are allowed to navigate forward and backward in the test can substantially complicate the definition of response time and the correct extraction of response time from the log files (Kroehne and Goldhammer, 2018). Furthermore, time limits at the item and/or test level, multiple attempts, and feedback can all have an impact on the definition, extraction, and comparability of response time.

Other issues to be taken into account when measuring response time are related to the time it took for the item to load on the screen, which may be hardware-dependent, or, if the test is administered online, dependent on the speed of the internet connection. An interesting aspect of response-time data is that even if test takers did not provide an item response, the log file may reveal how much time was spent on the item. Such information can be helpful in the treatment of missing data.

Fig. 1 shows a simplified four-stage process that represents what happens when an examinee visits an item. In the first stage, the item is initiated. Different events here pertain to loading the item on the screen. For example, images, text, and interactive elements (e.g., buttons, text boxes, spreadsheets, navigation) are loaded on the screen. In the second stage, the test taker can interact with the item (e.g., enter text response, mouse clicks, click next item). In stage three, scoring events (to the extent possible given the type of item administered) take place (e.g., scoring multiple-choice or numeric-entry response), including display of feedback. In stage four, the item session ends. Depending on what is allowed by the design, item sessions can be restarted (e.g., if items can be revisited). Now, for defining response time, the first time stamp can be the beginning of the item session, but can also be the beginning of the interaction. The second time stamp can be the end of the item session, but can also be the beginning of the scoring events. In any case, it is relevant to be aware of the exact definition of response time in order to be able to detect any issues in the response time data. For example, if the beginning of the interaction is used as the first time stamp, but navigation buttons can become active earlier, negative response times could show up in the data if one is not careful in the implementation of the exact definition of response time.

¹See www.imsglobal.org/question/index.html and www.wikipedia.org/wiki/QTI.

²See www.imsglobal.org/question/qti2p1/imsqti_infov2p1.html and www.wikipedia.org/wiki/ISO_8601.

Fig. 1 Simplified lifecycle of item session.

Fig. 2 shows an example of multiple item visits by a test taker. In this example, the test taker navigates from item 1 to 2, item 2 to 3, item 3 to 2, item 2 to 3, and item 3 to 4. Response times are recorded for four items in six item sessions. There are multiple ways to treat response time in this case. The most basic way is to sum the response times of item sessions that are associated with the same item. However, it may be relevant to see how this test taker split response time across the multiple visits, and perhaps to link this information with the response data (e.g., to see if the original response was changed in the second visit).

In sum, measuring response time in educational assessment is not always straightforward. One has to know the exact definition of response time and be aware of the potential impact of other design features on response time in order to be able to make the correct inferences from response-time data.

Modeling item response times

In this entry, we do not intend to provide the reader with a comprehensive overview of models for response time in educational assessment, but rather to give a list of modeling options to start out with. Extensive reviews of response-time models are provided by Lee and Chen (2011), van Rijn and Ali (2017), De Boeck and Jeon (2019), and Kyllonen and Zu (2016). Although the distinction between speed and power tests mentioned before is often made, most educational assessments have elements of both types with generally more focus on power. We distinguish two approaches to modeling item response times. In the first approach, a *separate* model is specified for response times. In the second approach, a *joint* model is specified for item responses and response times.

In addition to the distinction between separate and joint modeling approaches, three conceptual approaches can be distinguished (van Rijn and Ali, 2017). In the *statistical* approach, the focus is on adequate modeling of the observed distributions of item responses and response times (van der Linden, 2006, 2007). In the *measurement* approach, the goal is to formulate a scoring rule based on accuracy and speed that leads to a sufficient statistic of some latent proficiency (Maris and van der Maas, 2012; van Rijn and Ali, 2018a). In the *process* approach, the goal is to describe the cognitive process underlying the item responses (van der Maas et al., 2011). Although the starting points in these conceptual approaches are different, the resulting models do not necessarily have to be different.

Before discussing models, it is useful to establish some notational conventions. We denote the continuous random variable representing the response time for test taker i on item j by Y_{ij} and its realization by y_{ij} . The density of response time is denoted as $f(y_{ij})$ and the corresponding cumulative distribution is given by $F(y_{ij}) = \int_0^{y_{ij}} f(u)du$. Although response time can be discretized, the focus in this entry is on response time as a continuous variable. In addition, item responses are assumed to be discrete with the associated random variable denoted by X_{ij} . Finally, the number of test takers is denoted by n and the number of items by m .

Fig. 2 Example of test-taker path with multiple item visits.

Separate models for response times

We discuss three models for response times that are based on the log-normal, Weibull, and gamma distributions, respectively. Since observed response-time distributions are often positively skewed (due to the inevitable presence of some large values of response time), distributions that can accommodate skewness are typically chosen for modeling. Probably the most popular model for response times in educational assessments is the log-normal model. Although this model was popularized by [van der Linden \(2006\)](#), it was also used by [Thissen \(1983\)](#) and the log transformation for response times was suggested even much earlier ([Furieux, 1948](#); [Tate, 1950](#)). Other models for response time include the inverse Gaussian, ex-Gaussian, ex-Wald, and Gumbel distributions ([van Zandt, 2000](#); [De Boeck and Jeon, 2019](#)), but we focus on the aforementioned three to simplify our exposition.

Regardless of the chosen distribution, experts have recommended the use of parameters that can account for shift, scale, and shape to accurately capture observed response-time distributions ([Rouder et al., 2003](#)). In applications of response-time models in educational assessments, shift parameters relate to the minimum amount of processing time that is needed before any response can be produced (e.g., reading the item), scale relates to the variability in response times, and shape to skewness and kurtosis.

The log-normal model is given by

$$f(y_{ij} | \tau_i) = \frac{1}{y_{ij} \sigma_j \sqrt{2\pi}} \exp\left(-\frac{1}{2} \frac{[\log y_{ij} - (a_j + b_j \tau_i)]^2}{\sigma_j^2}\right), \quad (1)$$

where τ_i is a person parameter, and a_j , b_j , and σ_j^2 are item parameters. Equivalently, we can write $\log(y_{ij}) = a_j + b_j \tau_i + e_{ij}$ with $e_{ij} \sim N(0, \sigma_j^2)$. This model is essentially a normal linear factor model for $\log y_{ij}$ in which a_j is the intercept, b_j the factor loading, and σ_j^2 is the error variance ([Finger and Chee, 2009](#); [Molenaar et al., 2015a](#)). In the log-normal model described by [van der Linden \(2006\)](#), the factor loading b_j is fixed at -1, which allows for interpreting τ_i as a latent speed variable and a_j as the time intensity of item j . We shall refer to the van der Linden model as the one-parameter log-normal (1PLN) model and the model given by [Eq. \(1\)](#) as the two-parameter log-normal (2PLN) model. Further skewness can be accommodated by applying a one-parameter Box-Cox transformation to the response times ([Klein Entink et al., 2009](#)).

Different log-normal distributions for different types of item responses (such as correct and incorrect responses) can be specified without assuming a model for the item responses. In the following model, for example, the response times are allowed to be different for incorrect and correct responses ([Glas and van der Linden, 2010](#))

$$\log y_{ij} = a_j + b_j \tau_i + d_j x_{ij} + e_{ij}, \quad e_{ij} \sim N(0, \sigma_j), \quad (2)$$

where d_j is the additional item parameter and x_{ij} is the dichotomous item response with one for a correct response, and zero for an incorrect response. Other extensions of the log-normal model are possible, for example, by combining the extensions discussed above (e.g., a Box-Cox normal model with item response as predictor). However, the number of item parameters in such extensions can become quite large and large samples would be needed to obtain stable estimates.

The response-time model based on the three-parameter Weibull distribution is given by

$$f(y_{ij}) = \frac{k_j}{\lambda_j} \left(\frac{y_{ij} - c_j}{\lambda_j}\right)^{k_j-1} \exp\left[-\left(\frac{y_{ij} - c_j}{\lambda_j}\right)^{k_j}\right], \quad (3)$$

with parameters k_j for shape, λ_j for scale, and c_j for shift. In their model, [Tatsuoka and Tatsuoka \(1979\)](#) center the response times by $y_{ij}^* = y_{ij} - \bar{y}_i$, let $\tau_i + y_{ij}^*$, where τ_i is a person parameter, and fix $c_j = 0$ to simplify estimation. If the shape and scale parameters in [Eq. \(3\)](#) are fixed at 1, the model is similar to the exponential model by [Scheiblechner \(1979\)](#), which is given by $f(y_{ij} | \tau_i) = (\tau_i + a_j) \exp[-(\tau_i + a_j)y_{ij}]$.

The response-time model based on the gamma distribution is given by

$$f(y_{ij}) = \frac{y_{ij}^{k_j-1} \exp\left(-\frac{y_{ij}}{\lambda_j}\right)}{\lambda_j^{k_j} \Gamma(k_j)}, \quad (4)$$

with parameters k_j for shape and λ_j for scale, and $\Gamma(k_j)$ is the gamma function $\Gamma(k_j) = \int_0^\infty u^{k_j-1} \exp(-u) du$ for $k > 0$. [Maris \(1993\)](#) describes several models for response time based on the gamma distribution, assuming both additive and multiplicative relationships between item and person parameters.

We note that many other approaches can be used. Since response times can be considered to be durations, connections can be made to survival analysis (e.g., [Cox and Oakes, 1984](#)). We mention here the proportional-hazard modeling approach ([Ranger and Kuhn, 2012](#)) and the log-normal race model ([Rouder et al., 2015](#)). Also, if the interest is in modeling response times of correct responses only, special models can be constructed (see, e.g., [Muraki and Hagiwara, 2003](#); [Gaviria, 2005](#)). In addition, many different types of models can be constructed for special applications such as the Rasch Poisson model for reading speed ([Rasch, 1960](#), Chapter 3).

Alternatively, if the interest is in just fitting the response-time distribution and the sample is large, nonparametric methods such as Gaussian kernel estimators can be used ([van Zandt, 2000](#)). Such nonparametric methods can be useful for basic response-time

analysis (e.g., to evaluate timing issues or speededness), possibly combined with basic item-response analysis (e.g., to evaluate distractors and scoring). Particularly, such smoothing techniques allow for convenient graphical display.

Joint models for item responses and response times

Before discussing joint models, we briefly mention models for item responses. For dichotomously scored item responses, the following two-parameter setup can be employed

$$p(X_{ij} = 1 | \theta_i) = F[\alpha_j(\theta_i - \beta_j)], \quad (5)$$

where θ_i is a latent ability parameter, F is a (cumulative) distribution function, α_j is an item discrimination parameter, and β_j is an item difficulty parameter. Typical choices of F are the normal distribution and the more popular logistic distribution, referred to as the two-parameter logistic (2PL) model (Birnbaum, 1968). If the α_j are constant across items in the logistic model, the one-parameter logistic or Rasch model is obtained (Rasch, 1960). The three-volume handbook of item response theory (IRT) by van der Linden (2016) provides numerous other IRT models, including models with (pseudo-)guessing parameters, models for polytomous items, and multidimensional models.

In joint models, the focus is on modeling item responses and response times simultaneously. The speed-accuracy tradeoff (e.g., responses are less accurate if one is forced to work faster) is often taken into account in joint modeling. As noted in the introduction, however, this tradeoff originates from research on reaction times in experimental psychology and describes a within-person phenomenon resulting from performing tasks under different time limits. In educational assessments, it translates to a *speed-ability tradeoff* that can have both within- and between-person elements, but it can also be related to items and their positions in the test (van der Linden, 2009b; Goldhammer, 2015).

We discuss four different joint models for item responses and response times. The first model is the *hierarchical model* in which a model for item responses is combined with a model for response times (van der Linden, 2007). For example, the 2PL model can be used for item responses and the 2PLN model for response times. A bivariate normal distribution is assumed for latent ability θ and latent speed τ . This approach has been extended in several directions. For example, instead of IRT models, cognitive diagnostic models have also been used for item responses in combination with models for response time (e.g., Zhan et al., 2018). Furthermore, multidimensional latent variables can be specified for both ability and speed (Man et al., 2019).

The *Rasch response-time model* proposed by Roskam (1987, 1997) specifies the probability of a correct response as follows

$$p(X_{ij} = 1 | \theta_i, \gamma_{ij}) = \frac{\exp(\theta_i + \log \gamma_{ij} - \beta_j)}{1 + \exp(\theta_i + \log \gamma_{ij} - \beta_j)}, \quad (6)$$

where the log response time is used as a predictor of the item response. For response times, the following Weibull density is assumed:

$$f(\gamma_{ij} | \zeta_i, \theta_i) = \lambda_{ij} \gamma_{ij} \exp\left(-\frac{\lambda_{ij}}{2} \gamma_{ij}^2\right), \quad (7)$$

where $\lambda_{ij} = \frac{\exp(\theta_i)}{\exp(\beta_j) \zeta_i}$ and ζ_i is a person persistence parameter (van Breukelen and Roskam, 1991). A limitation of this model is the assumption that the probability of a correct response increases as response time increases, which makes the model suitable only for speed tests. A similar model was developed by Verhelst et al. (1997), making use of a gamma distribution for response time.

A different type of joint model can be specified if an explicit scoring rule is employed for the accuracy and speed of item responses. Maris and van der Maas (2012) used the signed-residual-time scoring rule that can be expressed as $s_{ij} = (2x_{ij} - 1)(h_j - \gamma_{ij})$, where h_j is the time limit for item j . In this scoring rule, fast correct responses are rewarded, while fast incorrect responses are penalized. A model in which this scoring rule is a sufficient statistic can be set up as

$$f(x_{ij}, \gamma_{ij} | \theta_i) = f(s_{ij} | \theta_i) = \frac{\exp(s_{ij} \eta_{ij})}{C(\eta_{ij})}, \quad (8)$$

where $\eta_{ij} = \alpha_j(\theta_i - \beta_j)$ and $C(\eta_{ij}) = \int_{-h_j}^{h_j} \exp(u \eta_{ij}) du$ is a normalizing constant (van Rijn and Ali, 2018a). This model, referred to as the *speed-accuracy response model*, is related to models for continuous item responses (Samejima, 1973; Müller, 1987; Verhelst, 2019).

Another joint model is the *diffusion model* (Ratcliff, 1978), which was mostly developed for two-choice memory retrieval tasks (Vandekerckhove et al., 2011), but has been applied in the context of ability testing (Tuerlinckx and de Boeck, 2005; van der Maas et al., 2011). In this model, the joint density of response accuracy and response time is given by

$$f(x_{ij}, \gamma_{ij} | \theta_i, \tau_i) = \frac{\pi}{B^2} \exp\left[BD\left(x_{ij} - \frac{1}{2}\right) - \frac{D^2}{2}(\gamma_{ij} - T_{nd})\right] \\ \times \sum_{k=1}^{\infty} k \sin\left(\frac{1}{2} \pi k\right) \exp\left[-\frac{\pi^2 k^2}{2B^2}(\gamma_{ij} - T_{nd})\right], \quad (9)$$

where B is a parameter referred to as boundary separation, D is the drift rate, and T_{nd} is the non-decision time. Here, we only mention the drift-diffusion model in which the boundary separation and drift rate are split into item and person parameters as follows: $D_{ij} = \theta_i - \beta_j$ and $B_{ij} = \tau_i/\alpha_j$. A simplified version of the diffusion model that eliminates the infinite sum in Eq. (9) is discussed by Boehm et al. (2021).

For the hierarchical model using the 2PL, the speed-accuracy response model, and the drift-diffusion model as discussed here, the marginal model for item responses is equivalent to a 2PL model (van Rijn and Ali, 2017). When joint models are used, it can be relevant to study the properties of the conditional item-response function $P(X_{ij} = 1|\theta_i, y_{ij})$ (also referred to as the conditional accuracy function) and the conditional response-time function $f(y_{ij}|\theta_i, x_{ij})$ for the purpose of model and parameter interpretation. However, we refrain from discussing such conditional functions here and refer to the original papers and comparisons described by Lee and Chen (2011), van Rijn and Ali (2017), and De Boeck and Jeon (2019). Finally, several other joint models and extensions exist, but the approaches discussed in this section should provide a good starting point. It is useful to keep in mind that several of the models can be framed as a multivariate generalized linear mixed model.

Estimation

Both frequentist and Bayesian estimation methods are generally available to estimate model parameters of the abovementioned models. The relationship of the log-normal models for response time with normal linear factor analysis (Lawley and Maxwell, 1971) greatly simplifies inference. However, this is not the case for some extensions of the log-normal model and other models for response times.

In the context of joint models, a number of assumptions are commonly made. For the hierarchical model, for example, the first assumption specifies that the response times for various items are independent of each other conditional on the latent speed variable, so that the joint conditional density can be written as a simple product. The second assumption specifies that item scores are independent conditional on the latent ability variable. Third, the item responses and response times are independent conditional on both latent variables (see van der Linden, 2007, p. 292). These three assumptions lead to the following simple product

$$f(\mathbf{x}_i, \mathbf{y}_i|\theta_i, \tau_i) = p(\mathbf{x}_i|\theta_i)f(\mathbf{y}_i|\tau_i). \quad (10)$$

In addition, a bivariate normal distribution is commonly assumed for latent variables θ and τ . Then, if we denote the model parameters by ξ , the marginal log-likelihood function is found by integrating out the latent variables as

$$\log L(\xi) = \sum_{i=1}^n \log \left[\int p(\mathbf{x}_i|\theta)f(\mathbf{y}_i|\tau)f(\theta, \tau)d\theta d\tau \right], \quad (11)$$

where the integral can be approximated using a Gauss-Hermite quadrature procedure. Maximum likelihood estimation can be carried out by finding the solution of the first-order derivatives set equal to zero. Details of marginal likelihood inference for the hierarchical model can be found in Glas and van der Linden (2010) and Kang et al. (2020).

The parameters of the speed-accuracy response model can also be estimated by maximizing its marginal log-likelihood function, which can be found under similar assumptions of conditional independence and a normally distributed latent variable. A computer program to estimate this model is described by van Rijn and Ali (2018b). Analogously, the parameters of the drift-diffusion model can be estimated by maximizing the marginal log-likelihood function. This method is implemented in the R package diffIRT (Moleenaar et al., 2015b).

Parameters of the hierarchical model can also be estimated with the method of moments by using an estimate of the covariance matrix. For example, the R package lavaan (Rosseel, 2012) can estimate the hierarchical model using least-squares methods if a normal ogive model is assumed for the item responses. This method is very flexible as it allows for easy generalizations to multi-dimensional models, inclusion of predictors, multi-group models, and correlated residuals.

Bayesian estimation can be performed after assuming prior densities for the model parameters, by applying Markov chain Monte Carlo (MCMC) methods. For the 1PLN, van der Linden (2006) used a Gibbs sampler to approximate the posterior densities. This approach is implemented for both 1PLN and 2PLN models in the R package LNIRT (<https://cran.r-project.org/web/packages/LNIRT/index.html>). Details of Bayesian inference for the hierarchical model can be found in van der Linden (2007) and this model can also be estimated in the R package LNIRT. However, the more general R package blavaan (<https://cran.r-project.org/web/packages/blavaan>) may be used as well.

Model fit

Depending on the purpose of modeling response times, different approaches to model fit may be relevant. For example, response time modeling for test security purposes (e.g., detecting item preknowledge) may require examining and evaluating different aspects of model fit than response time modeling for measurement purposes (e.g., improving measurement precision). Although many specific model features can be evaluated, we discuss three key elements with more focus on the fit to response times. The first element is that of the distributional assumption at the item level (e.g., see Eq. 1). Model fit can be evaluated by inspecting plots of the observed and predicted distributions of response times using estimated parameters, but P-P and Q-Q plots can be used as well. In addition, this type of fit can be summarized by using the root mean squared difference (RMSD) between observed and

predicted distributions at each ventile (i.e., 5th, 10th, ..., 95th percentile), as described by Schnipke and Scrams (1999). This approach is most useful when comparing different distributions, because the null distribution of RMSD is unknown.

Sinharay and van Rijn (2020) evaluated several statistics for testing the absolute fit of the log-normal model for response times. The Shapiro-Wilks test, which tests if log response time is normally distributed, was found to be the most powerful statistic for detecting item misfit. The statistic is based on order statistics and is easily computed using the R function `shapiro.test` (see <https://stat.ethz.ch/R-manual/R-devel/library/stats/html/shapiro.test.html>).

Residuals from estimated response-time functions similar to those for item-response functions developed by Haberman et al. (2013) can also be used to evaluate item fit. Under the log-normal model of Eq. (1), for example, the expected log response time as a function of τ for item j is $\hat{F}_j(\tau) = E(\log y_j | \tau) = \hat{b}_j - \hat{a}_j \tau$. An alternative estimate of this function can be defined as the ratio

$$\bar{F}_j(\tau) = \frac{\sum_{i=1}^n \log(y_{ij}) \hat{g}(\tau | y_{ij})}{\sum_{i=1}^n \hat{g}(\tau | y_{ij})}, \quad (12)$$

where the posterior $\hat{g}(\tau | y_{ij})$ is normal (Bartholomew, 1981, Eq. 5). A fixed number of values τ can be chosen based on its prior and posterior density. After defining the residual $r_j(\tau) = \bar{F}_j(\tau) - \hat{F}_j(\tau)$, a standardized residual can be computed as $z_j(\tau) = r_j(\tau) / \sigma[r_j(\tau)]$, where an estimate of the $\sigma[r_j(\tau)]$ can be found following Haberman et al. (2013, Eq. 46). Under the log-normal model, this standardized residual would converge in distribution to a standard normal variable, and plotting these as a function of τ should look like random scatter. A similar approach is available for the speed-accuracy response model (van Rijn and Ali, 2018a).

The second element of model fit relates to conditional-independence assumptions. In joint models, these assumptions can be tested both within items (e.g., item response and response time) and between items (e.g., item responses for item pairs, response times for item pairs). Glas and van der Linden (2010) describe an approach to evaluate the three conditional-independence assumptions for the hierarchical model mentioned in the section on estimation. They use Lagrange multipliers to develop tests against a specific alternative model for each of the three assumptions. For example, for testing conditional independence of item responses and response times conditional on both latent variables, the alternative model they used is that of Eq. (2). Alternatively, Sinharay and van Rijn (2020) found that a test on the difference between the observed and expected correlation between log response times for item pairs was quite powerful for testing the between-item conditional-independence assumption for response times. A benefit is that this test is easily obtained using the function `lavResiduals` in the aforementioned R package `lavaan`. For a critical discussion of conditional-independence assumptions in joint models, see Bolsinova et al. (2017).

The third element in evaluating model fit adheres to the assumed distributions for the latent variables in the model. Glas and Verhelst (1989) developed a chi-squared test statistic for the fit of the ability distribution in the Rasch model and its polytomous extension, the partial credit model. Monroe (2021) describes a method based on posterior residuals in the context of IRT models. To our knowledge, however, there is little research in a frequentist context on the fit of the latent speed distribution in both separate and joint models.

If Bayesian methods are used, model fit can be evaluated using, for example, Bayesian model fit and model selection tools such as Bayes factors and posterior predictive model checking (e.g., Sinharay et al., 2006).

Illustration

The purpose of this illustration is to provide a simple demonstration of how different distributions and models for response times can be compared. We analyzed data obtained from 9355 test takers to 17 four-choice items of one out of two sections of a listening test, which is part of a test of English language ability used for international students (van Rijn and Ali, 2018b). Test takers had 10 min to answer all 17 items in this section of the test.

To illustrate the different distributions for response time described earlier, we fit log-normal, Weibull, and gamma distributions to the response-time data of each item. Following Schnipke and Scrams (1999), we summarized the fit using the root mean squared difference (RMSD) between observed and predicted distributions at each ventile (i.e., 5th, 10th, ..., 95th percentile). The mean and standard deviation (SD) of this statistic across all 17 items are shown for the three distributions in Table 1. The log-normal distribution seems to fit best in the sense that it has smaller mean RMSD values than the other two distributions both overall, and for incorrect and correct responses separately. To further illustrate the differences between the distributions, Fig. 3 shows histograms of response time and fitted log-normal, Weibull, and gamma densities for correct responses of four items. Items 2 and 10 were selected because they had relatively high RMSD values (0.043 and 0.051, respectively, for the overall log-normal), while items 3 and 14 had relatively low values (0.015 and 0.010, respectively, for the overall log-normal). Gaussian kernels were also fitted using the R function `density` and added to the plots (RMSDs were not computed). Not surprisingly, the Gaussian kernels appear to fit best, but these cannot be used in further modeling. Generally, the graphical results are in line with those in the table in that the log-normal distribution outperforms the Weibull and gamma distributions, which supports the use of the log-normal model in further modeling.

We used the R package `lavaan` to fit the log-normal model of Eq. (1) to the response times and evaluated model fit. The CFI is 0.802 and the RMSEA is 0.056, indicating poor model fit (Rigdon, 1996). We used the R function `shapiro.test` on a random subsample of 1000 test takers instead of the full sample to avoid detection of very small effects. Nevertheless, the test on the log

Table 1 Mean RMSD (SD) for log-normal, Weibull, and gamma distributions across 17 items of listening test.

Distribution	Mean RMSD (SD)		
	Overall	Incorrect	Correct
Log-normal	0.021 (0.012)	0.012 (0.003)	0.026 (0.015)
Weibull	0.053 (0.013)	0.038 (0.010)	0.061 (0.015)
Gamma	0.034 (0.014)	0.015 (0.006)	0.042 (0.016)

response time for each item returns 17 out of 17 significant results at the 0.05 level. So, even though the log normal distribution produced lower RMSD values and better fitting densities than the other two distributions, there still seem to be issues with model fit at the item level (e.g., due to differences in response-time distributions for incorrect and correct responses). In addition, the z-test for conditional independence on the full sample results in 98 significant results at the 0.05 level out of 136 pairs of response times. Of course, the sample size is rather large here and the power to detect misfit is substantial.

Notwithstanding these model fit results, we continued with fitting the hierarchical model for which we also used the lavaan package. This resulted in a CFI of 0.817 and an RMSEA of 0.062, again indicating poor model fit. The estimated correlation between latent ability and latent speed was 0.40, so higher ability is associated with higher speed in this case. In order to improve model fit, we allowed different response-time distributions for incorrect and correct answers. To this end, we fit the hierarchical model with the dichotomous item response as a predictor of response time as in Eq. (2). This resulted in a CFI of 0.930 and an RMSEA of 0.039, a drastic improvement. The latent correlation between ability and speed was estimated at 0.04. Noteworthy is that all 17 additional

Fig. 3 Histogram of response times of correct responses with fitted log-normal, Weibull, gamma, and Gaussian kernel densities for four listening items.

regression parameters were significantly different from zero, which may explain the misfit discussed above. Alternatively, the original hierarchical model can also be relaxed by allowing residual correlations between item responses and response times within items, in which case the CFI becomes 0.870, RMSEA 0.053, and latent correlation 0.33. Although this is a substantial improvement compared to the original hierarchical model, it is not as good as the hierarchical model with item response as predictor.

Discussion

In this entry, we discussed both practical and theoretical aspects of measuring and modeling item response times in educational assessment. We discussed both separate models for item response times and joint models for item responses and response times. We briefly discussed methods for estimation and evaluating model fit. Response times can provide valuable information in addition to item responses, but poor model fit can be an issue, as shown in the illustration. Notwithstanding fit issues, models ultimately need to be judged based on their utility as well (Box, 1976) and the practical implications of misfit should be carefully evaluated before discarding them. In addition, the extent to which misfit has a practically significant impact depends on how response time is used (i.e., collateral vs. essential to the assessment outcome). The approach described by Sinharay and Haberman (2014) for IRT models in which practically significant misfit is determined by whether a better-fitting model leads to different decisions based on test scores can be tailored to models for response times.

In closing this entry, we would like to point out some topics that may guide readers in further study and research on modeling item response times. The generalized linear factor modeling framework described by Molenaar et al. (2015c) could be developed further. It can especially include more distributions for response time, as most distributions we discussed fit into the exponential family. Furthermore, the evaluation and relaxation of conditional-independence assumptions has been an active area of research (Bolsinova et al., 2017); although this research has focused mostly on within-item conditional independence of item responses and response times, there are examples of between-item studies (e.g., Li et al., 2012). Finally, mixture modeling approaches can be useful if one is interested in distinguishing different unobserved classes of response behaviors and processes (Molenaar and de Boeck, 2018).

Introduction

In psychological and educational measurement, many researchers use rating scales to assess abilities, personality dispositions, attitudes, beliefs, or opinions. However, observed rating responses reflect not only the latent construct that is to be measured, but the responses are also influenced by the respondents' interpretation and use of the rating categories (Baumgartner and Steenkamp, 2001). Examples of such response tendencies or *response styles* are the preference for extreme categories (i.e., extreme response style, ERS) or for the middle category (i.e., midscale response style, MRS), or the tendency to agree with the item independent of item content (i.e., acquiescent response style, ARS; e.g., Couch and Keniston, 1960; Cronbach, 1942; Hamilton, 1968; Hui and Triandis, 1985; Paulhus, 1991; Rost et al., 1999; Van Vaerenbergh and Thomas, 2013).

The awareness of response styles, and the interest in controlling their effects to safeguard valid measurement, have increased in recent years. Because it has been shown that response styles exert substantial effects on rating responses (e.g., Adams et al., 2019; Böckenholt and Meiser, 2017; Bolt and Johnson, 2009) and that individual differences in response styles are stable over content domains and over time (Van Vaerenbergh and Thomas, 2013; Weijters et al., 2010a, 2010b; Wetzel et al., 2013b), response styles may put data quality at risk. Hence, if unaccounted for, response styles can bias the measurement of latent constructs in educational research. For instance, they can influence diagnostic decisions through biasing individual estimates (Bolt et al., 2014; Plieninger, 2017), inflate relations between trait estimates or total scores (Böckenholt and Meiser, 2017), and affect group comparisons in cross-cultural research (De Jong et al., 2008; Moors, 2004; Morren et al., 2012; van Herk et al., 2004).

Early attempts to control for response styles used descriptive statistics, such as the number of extreme categories to measure ERS (Bachman and O'Malley, 1984; Cronbach, 1942; Greenleaf, 1992). Later, latent variable models, such as Structural Equation Models (SEM) or Item Response Theory (IRT) models, were extended to incorporate, and therewith account for, response styles. For example, mixture distribution IRT models allowed item parameters to differ between latent subpopulations (Rost, 1991) and hence, they can be used to identify subpopulations that use the rating scale in different ways. Indeed, applications of mixture models have identified two major subpopulations: one subpopulation with moderate response behavior preferring non-extreme categories, and one subpopulation with a preference for extreme response categories (e.g., Meiser and Machunsky, 2008; Moors, 2003; Wetzel et al., 2013a). However, although the identification of unknown latent subpopulations of respondents is an interesting characteristic of mixture distribution models, the assumption of categorical response style types (such as a type of moderate responders vs. a type of extreme responders) appears too strict and implausible given that most psychological and educational constructs are continuous in nature.

Consequently, several approaches have been proposed to incorporate response styles as continuous dimensions in IRT models, and these approaches will be the focus of the present chapter. First, IRT models for ordinal responses have been extended by additional response style dimensions accompanying the constructs of interest (e.g., Bolt and Newton, 2011; Falk and Cai, 2016; Henninger and Meiser, 2020a; Wetzel and Carstensen, 2017). Second, by decomposing rating responses into multiple discrete judgments with appropriate IRT representations, so-called IRTree models reflect response processes that are related to the traits of interest and to response styles as continuous dimensions (e.g., Böckenholt, 2012; De Boeck and Partchev, 2012; Khorramdel and von Davier, 2014; Meiser et al., 2019).

Besides modeling response styles as continuous dimensions, extended IRT models for ordinal responses and IRTree models have several advantages in common. First, both approaches are flexible in accounting for numerous variants of response styles. Second, they allow researchers to specify, model, and test specific theoretical assumptions about response styles in a confirmatory way. Third, each approach enables researchers to estimate latent correlations between the traits of interest and response styles. Fourth, both modeling approaches are easy to implement in existing software packages. And finally, even though we focus on the modeling

of response styles in this chapter, both modeling approaches can easily be adapted and extended to model other response tendencies or processes, such as socially desirable responding, missing responses, or test quitting behavior (see e.g., Falk and Cai, 2016; Jeon and De Boeck, 2016). Despite their common advantages, multidimensional IRT models and IRTree models for response styles differ in decisive ways, as will be discussed in the following sections.

The chapter is structured as follows. In the next sections, we provide introductions into multidimensional extensions of ordinal IRT models (Section **Multidimensional extensions of ordinal IRT models**) and into IRTree models (Section **IRTree models**) that accommodate response styles. In the remainder, we illustrate the similarities and differences of ordinal IRT and IRTree models for response styles using background questionnaire data from the PISA study 2018 (Section **Empirical illustration**). In the final discussion (Section **Discussion**), we summarize further modeling extensions, critical aspects for model application, and alternative response formats as a remedy of response style effects.

Multidimensional extensions of ordinal IRT models

Responses to rating scales (e.g., with $K + 1$ response categories $k \in \{0, \dots, K\}$) can be described through IRT models for ordinal data, such as the Graded Response Model (GRM; Samejima, 1969) and models from the Divide-by-Total model family (Thissen and Steinberg, 1986), such as the Nominal Response Model (NRM; Bock, 1972; Takane and de Leeuw, 1987), the Partial Credit Model (PCM; Masters, 1982), or the Rating Scale Model (RSM; Andrich, 1978).

These modeling approaches describe the probability that respondent n chooses category k in item i as a function of a latent person parameter θ_n describing the respondent's level on the construct of interest, an item location parameter β_i , and an item-specific threshold parameter τ_{ik} . Here we present the PCM as one typical model that can be used for ordinal rating data in further detail: In the PCM (adapted from Masters, 1982), the probability of choosing a certain category k is given by

$$p(X_{in} = k) = \frac{\exp\left(s_k \theta_n - \sum_{k'=0}^k (\beta_i + \tau_{ik'})\right)}{\sum_{j=0}^K \exp\left(s_j \theta_n - \sum_{k'=0}^j (\beta_i + \tau_{ik'})\right)} \quad (1)$$

with $\sum_{k=1}^K \tau_{ik} = 0$. The scoring weights s_k describe the relation between the latent person parameter and the observed category, and in the PCM they are usually fixed to $s = (0, \dots, K)$ for the $K + 1$ categories to reflect the ordinal nature of rating data. For example, for an item with 4 response categories, scoring weights can be fixed to $s = (0, 1, 2, 3)$. For identification, the sum of the item and threshold parameter for the first response category $k = 0$ is set to zero, that is, $(\beta_i + \tau_{i0}) \equiv 0$. The denominator of Eq. (1) accumulates the exponential of the linear parameter combination for each category, which ensures that the sum of all category probabilities is equal to 1 for all values of θ .

Fig. 1 shows the *category characteristic curves* (CCCs) for an item with 4 response categories (e.g., 0: “strongly disagree”, 1: “disagree”, 2: “agree”, 3: “strongly agree”), where each CCC depicts the probability of a response category for a given item location and set of thresholds as a function of the person parameter θ . The concept of category probabilities is best illustrated in the middle panel of Fig. 1 that shows the CCCs in the case of a neutral response style. For instance, respondents with a person parameter of $\theta_n = 1$ have the highest probability for the “agree” category as compared to the other categories, while for respondents with person parameter $\theta_n = 2$, it is most likely that they choose the “strongly agree” category. At the same time, the model is probabilistic, meaning that it makes a prediction for the most probable category, but also allows that other categories are chosen with a smaller probability.

Fig. 1 Category characteristic curves for an item with four response categories (Cat. 0 to Cat. 3) and low (left), intermediate (middle), and high (right) levels of extreme response style.

Eq. (1) can be used to model responses to rating scales of ordinal nature. However, to accommodate response styles, the model equation must be extended to incorporate additional dimensions that reflect the way respondents use the rating categories. Hence, in multidimensional PCMs (and also in multidimensional GRMs, NRMs, or RSMs), additional latent dimensions can be specified that capture systematic influences on item responses other than individual differences in θ . For example, we can assume that not only the construct we are interested in, but also the ERS level influences the selection among the “strongly disagree” versus “disagree” categories, and among the “agree” versus “strongly agree” categories, respectively. Similarly, for rating scales with uneven numbers of response categories, a response in the middle category may not only depend on the construct level θ , but also on the respondent’s MRS level (see e.g., Bolt and Newton, 2011; Falk and Cai, 2016; Henninger and Meiser, 2020a, 2020b; Wetzel and Carstensen, 2017).

In an extended model that accommodates extreme responding with an additional ERS dimension, the category probabilities can be specified as

$$p(X_{in} = k) = \frac{\exp\left(s_k \theta_n - \sum_{k'=0}^k (\beta_i + \tau_{ik'}) + s_k^{\text{ERS}} \theta_n^{\text{ERS}}\right)}{\sum_{j=0}^K \exp\left(s_j \theta_n - \sum_{k'=0}^j (\beta_i + \tau_{ik'}) + s_j^{\text{ERS}} \theta_n^{\text{ERS}}\right)} \quad (2)$$

The scoring weights of the response style dimension (here s_k^{ERS}) define which categories are influenced by the response style level. For example for an item with four response categories, the scoring weights for ERS can be set to $s_k^{\text{ERS}} = (1, 0, 0, 1)$ indicating that positive levels of θ_n^{ERS} increase the probability of choosing one of the extreme categories, while negative levels of θ_n^{ERS} decrease the probability for an extreme response.

The left and right panels of Fig. 1 illustrate how the response style dimension θ^{ERS} affects the category probabilities, where CCCs are displayed for low and high levels of ERS, respectively. When ERS is low, the probability of passing the first threshold increases, while the probability of passing the last threshold decreases (first and last vertical line), making the non-extreme categories the modal categories over a larger range of θ as compared to a neutral response tendency (middle panel). The opposite applies in the case of high ERS: The extreme categories become more likely for smaller and larger values of θ as it is harder to pass the first, and more difficult to pass the last threshold (see also Henninger and Meiser, 2020a, 2020b, for an extensive discussion).

Hence, multidimensional IRT models allow for different levels of response styles, so that the probability of choosing a certain category does not only depend on the person parameter θ , but also on a respondent’s value on the response style dimension. For instance, in Fig. 1 a respondent with $\theta_n = 1$ and *low* ERS level (left panel) has the highest probability for choosing the “agree” category (Cat. 2), while a respondent with the same person parameter $\theta_n = 1$ and *high* ERS level (right panel) has the highest probability for choosing the “strongly agree” category (Cat. 3).

In Fig. 1 and in the empirical example below, we use responses to 4-point rating scales to illustrate IRT models that incorporate response styles, because 4-point rating scales are commonly used in the background questionnaires of the PISA studies and in other educational assessments. To model response styles in 4-point rating scales, researchers usually add only an ERS dimension (see Eq. (2)), although preferences for other categories can be considered in an analogous way. When the data is based on rating scales with five or more response categories (as is typical in the measurement of personality constructs, such as the Big Five), there is more flexibility in the modeling of various types of response styles. For instance, Table 1 shows exemplary scoring weights for the construct of interest θ as well as for ERS and MRS in items with a five-point rating scale (see also Bolt and Newton, 2011; Falk and Cai, 2016; Henninger, 2020; Wetzel and Carstensen, 2017, for further examples of scoring weights). Besides the typical response styles ERS and MRS, scoring weights can be used to specify other types of response tendencies, such as ARS through $s_k^{\text{ARS}} = (0, 0, 0, 1, 1)$, socially desirable responding (see e.g., Falk and Cai, 2016), individually varying thresholds (Henninger, 2020; Wang et al., 2006), or preferences for specific categories (Adams et al., 2019; Bolt et al., 2014). For overviews on how scoring weights can be defined to reflect different types of response tendencies, see Falk and Cai (2016) and Henninger and Meiser (2020a, b).

IRTree models

Following the rationale of decision trees, IRTree models decompose rating responses into a series of underlying judgments that terminate in the choice of an observed category (Böckenholt, 2012; De Boeck and Partchev, 2012). The judgments can be specified

Table 1 Scoring weights for different constructs and response styles in items with five response categories $k \in (0, \dots, 4)$.

	$k = 0$	$k = 1$	$k = 2$	$k = 3$	$k = 4$
$s_{\text{Construct}}$	0	1	2	3	4
$s_{\text{Construct(Reversed Items)}}$	4	3	2	1	0
s_{ERS}	1	0	0	0	1
s_{MRS}	0	0	1	0	0

Fig. 2 IRTree structure for 5-point rating items with midscale, agreement and extreme response judgments.

as decision nodes which reflect trait-based response processes of endorsing the item content and general response tendencies affecting the selection of categories. For a 5-point rating item as in [Table 1](#), [Fig. 2](#) shows an IRTree structure with three judgment processes (for applications, see [Böckenholt, 2012](#); [Khorramdel and von Davier, 2014](#); [Zettler et al., 2016](#)). The first node refers to the decision to choose the midscale response 2 as opposed to a rating category of either disagreement (i.e., 0 or 1) or agreement (i.e., 3 or 4). If a respondent does not choose the midscale category, they decide between disagreement or agreement with the item at the second node. The third decision node relates to the selection of an extreme versus non-extreme response category given a disagreement or agreement judgment.

The assumed latent judgment processes of an IRTree model are specified by means of virtual pseudo-items together with an IRT parameterization for each decision node, as illustrated in [Table 2](#). Concerning response X_i to rating item i , the first node in [Fig. 2](#) can be represented via a binary pseudo-item Y_{1i} which takes on value 1 if the midscale category is chosen and 0 otherwise. Likewise, the second node can be captured by a pseudo-item Y_{2i} which is scored 1 for a non-extreme or extreme agreement response, 0 for the two disagreement responses, and missing for midscale responses. The third judgment, finally, can be represented through a pseudo-item Y_{3i} with value 1 for extreme responses and value 0 for non-extreme responses of agreement or disagreement. The pseudo-items of an IRTree model are parameterized with an appropriate IRT model, like the Rasch, 2 PL or probit model, with separate person parameters for the assumed judgment processes. The probability of observing category k in rating item i for respondent n , $p(X_{in} = k)$, follows from multiplying over the model probabilities of the pseudo-items that are involved in the category response (for details, see [Böckenholt and Meiser, 2017](#); [Jeon and De Boeck, 2016](#)). [Table 2](#) illustrates the parameterization of pseudo-items with the Rasch model, including person parameters for midscale responding θ^{MRS} , agreement with the item content θ , and extreme responding θ^{ERS} . The table also shows the model equation of the category probabilities for the IRTree structure in [Fig. 2](#).

For rating items with four categories that are often used in educational studies, the midscale judgment can be omitted, yielding an IRTree model with two latent dimensions of agreement θ and extreme responding θ^{ERS} ([Kim and Bolt, 2021](#); [Plieninger and Meiser, 2014](#)). The IRTree structure follows from the diagram in [Fig. 2](#) if the first node is dropped and the remaining terminal nodes are relabeled as categories $k = 0, \dots, 3$. The corresponding definition of binary pseudo-items and their parameterization with the Rasch model are displayed in the upper panel of [Table 3](#).

Like in [Table 2](#), the pseudo-items for 4-point rating scales in [Table 3](#) maintain the assumption that the extremity judgment is based on a unidimensional person dimension θ^{ERS} . Inasmuch as the selection of an extreme response category of disagreement or agreement is driven by (a) the tendency to prefer extreme response options and (b) the strength of the trait that is measured by the item, however, θ^{ERS} reflects a confound of the general response style and the specific trait of interest. We therefore used multidimensional parameterizations of the IRTree node probabilities (see also [Böckenholt, 2019](#); [Jeon and De Boeck, 2016](#); [von Davier and Khorramdel, 2013](#)) to account for the joint influence of the response style and the target trait in the choice of (non-)extreme response categories ([Meiser et al., 2019](#)). For this purpose, the pseudo-item of extremity has to be split into separate pseudo-items for the disagreement and agreement categories to allow for different signs of the target trait θ , as displayed in the lower panel of [Table 3](#): According to the ordinal nature of the rating scale, the probability of the extreme category 0 should decrease with increasing values of θ , whereas the probability of extreme category 3 should increase for larger values of θ . Hence, θ has a negative sign for judgments of extreme disagreement but a positive sign for judgments of extreme agreement. In addition, θ is weighted by the parameter $\alpha_{\text{dis}} > 0$ in the pseudo-item of extreme disagreement and by $\alpha_{\text{ag}} > 0$ in the pseudo-item of extreme agreement to allow for a differential impact of the target trait on the overall agreement judgment in the first node and on the gradual judgments of disagreement and agreement in the subsequent nodes. To summarize, the IRTree model with multidimensional extremity nodes in the lower panel of [Table 3](#) combines an ordinal trait-based response process over the full range of the rating scale with an individual tendency of response extremity.

Extremity	1	0	–	–	$\frac{\exp(\theta_n^{\text{ERS}} - \alpha_{\text{dis}} \theta_n - \beta_{2i})}{1 + \exp(\theta_n^{\text{ERS}} - \alpha_{\text{dis}} \theta_n - \beta_{2i})}$
	–	–	0	1	$\frac{\exp(\theta_n^{\text{ERS}} + \alpha_{\text{ag}} \theta_n - \beta_{2i})}{1 + \exp(\theta_n^{\text{ERS}} + \alpha_{\text{ag}} \theta_n - \beta_{2i})}$

Empirical illustration

In this section, we demonstrate that response styles are a substantial variance component of rating data in the field of education. The following analyses use data from the Program for International Student Assessment (PISA) and illustrate how psychometric models can help researchers to account for ERS in the estimation of latent constructs. In addition, we compare the multidimensional extension of the PCM with the IRTree model and demonstrate to what extent the approaches differ with respect to the estimation of person parameters and estimated correlations between latent constructs.

For the empirical illustration, we selected two subscales about reading from the background questionnaire¹ of the PISA 2018 study.² The “reading enjoyment” scale (ST160) contains five items including three inverted items, while the “reading self-evaluation” scale (ST161) contains six items with three inverted items. The selection of these two scales allows us, first, to model different constructs at the same time, and second, to use scales with reverse-coded items. Both aspects facilitate the separation of construct and response style dimensions when estimating response style models and are hence recommended modeling strategies for multidimensional PCMs and IRTree models (see e.g., Henninger and Meiser, 2020b). All items had a 4-point response format with categories from “strongly disagree” to “strongly agree”. For the present analyses, we selected data from native English speaking US participants. We paid careful attention to retain only valid data and therefore removed participants with incomplete data and those who did not select at least three different response categories over the selected items. The final sample comprised data from $N = 4,411$ participants from the US that gave responses to the 11 items.

All analyses reported below were conducted with the R package `mirt` (Chalmers, 2012) using the EM algorithm with 25 quadrature points. Full latent variance-covariance matrices were estimated to allow for correlated reading constructs and response style dimensions. Inverted items were recoded prior to the analyses.³ Exemplary R code, that allows users to apply the models presented here to their own data, is provided on OSF.⁴

¹https://nces.ed.gov/surveys/pisa/pisa2018/questionnaires/Student_Q_Booklet_English.html.

²<http://www.oecd.org/pisa/data/2018database/>.

³As an alternative to recoding inverted items prior to model specification, original responses can be analyzed with scoring weights $s^{\text{Construct Reversed}} = (3, 2, 1, 0)$ for reversed-coded items, as shown in Table 1.

⁴<https://osf.io/bu5qt/>.

Multidimensional extension of the PCM

To illustrate the estimation and interpretation of a multidimensional extension of the PCM, we fit two models, one ignoring ERS and one accounting for ERS according to Eqs. (1) and (2). Model 1 is a two-dimensional PCM with the items from the two scales “reading enjoyment” and “reading self-evaluation” each defining one latent dimension. Model 2 is an extension of Model 1 with an additional dimension that accounts for ERS. The scoring weights were fixed to $s^{\text{Construct}} = (0, 1, 2, 3)$ for the two reading dimensions and to $s^{\text{ERS}} = (1, 0, 0, 1)$ for the ERS dimension. Table 4 shows the log-likelihood, number of estimated parameters, AIC and BIC for the two models.

Model comparisons with the likelihood ratio test ($\chi^2 = 2819.33, df = 3$) and the information criteria AIC and BIC indicated that Model 2 fits the data better than Model 1, corroborating the role of ERS. Moreover, the latent correlations show that the two reading dimensions are substantially related, $\hat{\rho} = .44$, while the ERS dimension forms a distinct factor with weaker relations to the two reading dimensions, $\hat{\rho} = .23$ and $\hat{\rho} = .16$. In addition, Model 2 shows substantial variance of the ERS dimension ($\hat{\sigma}^2 = 1.96$), compared to the two reading dimensions ($\hat{\sigma}^2 = 4.00$ and $\hat{\sigma}^2 = 2.58$).

Fig. 3 illustrates the impact of ERS on rating responses. Panel A shows the observed relative frequencies of each category for three subgroups of respondents with different ERS levels based on ERS estimates in Model 2. From left to right, the columns show the relative frequencies of category choices for the 20% of respondents with lowest ERS levels, for respondents with intermediate ERS levels, and for respondents with the highest ERS levels (80% to 100% quantiles). We can see that the distribution of category choices differs substantially between the three subgroups, where respondents with low ERS levels tend to avoid the extreme categories, while respondents with high ERS levels tend to overselect the extreme categories. Panel B shows the construct estimates of the reading enjoyment scale based on a PCM ignoring ERS (x-axis) and the PCM accounting for ERS (y-axis). The color shades indicate the ERS level based on ERS estimates in Model 2. We can see that by accounting for ERS through the multidimensional model, low reading enjoyment estimates are corrected downwards for low ERS levels (light blue circles), but they are corrected upwards for high ERS levels (dark blue squares). For high estimates, in contrast, the correction works in the opposite direction, such that larger estimates result for low ERS and smaller estimates for high ERS. Thereby, the multidimensional PCM accounts for an over- or underselection of the extreme categories through an extreme response tendency.

IRTTree models

From the class of IRTree models, the model with unidimensional nodes of agreement and extremity in the upper panel of Table 3 was applied to the reading data as Model 3, and the model with two-dimensional nodes of extremity in the lower panel of Table 3 was applied as Model 4. As in the case of the PCMs above, separate dimensions were specified for the items of the subscales “reading enjoyment” and “reading self-evaluation”. The analysis allowed us to compare the two versions of the IRTree model, and it afforded comparisons of parameter estimates between the IRTree that accommodates ERS and the standard PCM that does not capture response styles.⁵ Fit indices of the Models 3 and 4 are displayed in Table 4.

The traditional IRTree Model 3 with unidimensional node parameterizations showed a similar estimated variance-covariance matrix as the extended PCM, including substantial variance of the ERS dimension ($\hat{\sigma}^2 = 1.84$), compared to the two reading dimensions ($\hat{\sigma}^2 = 5.57$ and $\hat{\sigma}^2 = 3.70$).

The latent correlation of the two reading dimensions amounts to $\hat{\rho} = .48$, and their estimated correlations with the latent ERS dimensions are $\hat{\rho} = .15$ and $\hat{\rho} = .31$. The notable correlations of the reading constructs with the response style dimension hint at the potential confound of the reading dimensions and the response style in the factor θ^{ERS} of Model 3. Model 4, in contrast, separates effects of the target traits and of ERS in the pseudo-item for extreme disagreement and agreement. As can be seen in Table 4, Model 4 provides a better fit to the reading data as compared with the traditional IRTree Model 3. Moreover, due to accounting for

Table 4 Model fit of the ordinal IRT models and IRTree models for response styles.

	Log-likelihood	Parameters	AIC	BIC
Model 1: two-dimensional PCM ignoring ERS	− 49,160.73	36	98,393.47	98,623.58
Model 2: three-dimensional PCM with ERS dimension	− 47,751.07	39	95,580.14	95,829.43
Model 3: IRTree model with unidimensional nodes	− 50,872.82	28	101,801.60	101,980.60
Model 4: IRTree model with multidimensional nodes	− 48,422.44	32	96,908.88	97,113.42

⁵Please note that the two-dimensional PCM ignoring ERS is a special case of the three-dimensional PCM accounting for ERS within the same model class. However, there is no equivalent restriction of the IRTree model one could directly compare the IRTree model to. Therefore, we use the construct estimates of the PCM ignoring ERS for comparison (see e.g., Böckenholt, 2017, for a similar approach).

Fig. 3 Panel A: relative frequencies of response category choices for lower and upper 20% quantiles and intermediate levels of Extreme Response Style (ERS) based on ERS estimates in Model 2; Panel B: correction of “Reading Enjoyment” estimates when ERS is accounted for by Model 2 (Multidimensional PCM with ERS dimension). Panel C and D: as Panels A and B but based on the ERS estimates in Model 4; Panels E: “Reading Enjoyment” estimates when ERS is accounted for by Model 4 (IRTTree model with multidimensional nodes) compared to a PCM accounting for ERS.

both the substantive traits and ERS in the extremity node, Model 4 accomplishes a clear distinction between the trait and ERS factors: $\hat{\rho} = .46$ for the correlation among the two reading dimensions, and $\hat{\rho} = .002$ and $\hat{\rho} = -.006$ for the correlations of the two reading dimensions with the latent ERS dimension.

Panel C in Fig. 3 shows how different subgroups of respondents with varying ERS levels in the IRTree Model 4 with multidimensional nodes differ in their category choices. Panel D shows the de-biasing role of Model 4 with respect to the “Reading Enjoyment” estimates in comparison to the PCM ignoring ERS. As both model correct the estimates for the biasing effect of ERS, the frequencies of category choices (Panels A and C) as well as the correction of trait estimates (Panels B and D) are highly similar between the two

modeling approaches. The similarity can also be seen in Panel E, where the “Reading Enjoyment” estimates from the multidimensional PCM accounting for ERS and the IRTree model with multidimensional nodes are directly compared to each other.

Comparison of extended PCMs and IRTrees

The extended PCM and the IRTree models have shown substantial variance of the latent ERS dimension, attesting to the role of the response tendency across the items of the two reading subscales. In addition, Fig. 3 has illustrated how ERS influences response behavior, and that extended PCMs and IRTree models allow researchers to correct construct estimates from biasing ERS effects.

Although the two approaches to modeling response styles have several commonalities and differences, a direct comparison of multidimensional PCMs and IRTrees for response styles is precluded by the different structures of the likelihood functions and by different kinds of restrictions. Looking at the multidimensional PCM Model 2 and the IRTree Model 4 with multidimensional nodes, Model 2 is more restrictive in terms of equal discrimination parameters across categories and thresholds, whereas Model 4 allows for different weights of θ for extreme disagreement and extreme agreement. In contrast, Model 4 is more restrictive than Model 2 in terms of equal threshold parameters for extreme responses at either side of the rating scale, whereas the multidimensional PCM does not include restrictions on the threshold parameters.

Beyond the specific model definitions and restrictions used in the present illustration with 4-point rating data, both multidimensional PCMs and IRTree models form flexible modeling frameworks that allow researchers to specify a range of theoretical assumptions for a variety of rating response formats.

Discussion

We have presented and illustrated two different modeling classes that incorporate and control for response styles: multidimensional extensions of ordinal IRT models and IRTree modeling approaches. Both modeling classes have advantages and disadvantages with respect to the modeling of response styles that we would like to highlight and discuss.

An advantage of multidimensional extensions of ordinal models, such as PCMs, is that they retain the ordinal scoring for content traits. Hence, they allow that, for instance, a response in the “strongly agree” category is influenced by both, a positive level of the construct to be measured and a positive level of ERS. Another advantage is that multidimensional PCMs do not require to restructure the data, as scoring weights can be used to specify how each of the categories is related to the latent dimensions. Besides, scoring weights allow the applicant of this model family to flexibly specify additional response style dimensions to be accounted for. In this chapter, we presented scoring weights for the most commonly investigated response styles ERS and MRS, but other types such as ARS (see Falk and Cai, 2016; Henninger and Meiser, 2020b), varying thresholds (Henninger, 2020; Wang et al., 2006) or socially desirable responding (Falk and Cai, 2016) can also be incorporated into the IRT model with specific definitions of scoring weights. Please note that when scoring weights are fixed in a way that they are not redundant to the construct of interest, the covariance matrix between constructs and response style dimensions can be estimated and interpreted to evaluate whether the constructs of interest are related to certain response tendencies.

Similar to multidimensional PCMs, IRTree models provide the opportunity to flexibly specify different subprocesses through recoding of the original responses into specific pseudo-items. Therewith, IRTrees cannot only account for ERS or MRS, but also for other response processes such as not-reached or omitted responses (De Boeck and Partchev, 2012). Like in multidimensional extensions of PCMs, the latent covariance matrix between the trait and response style dimensions can be estimated and interpreted. An advantage of IRTrees over multidimensional PCM is the direct interpretation of person and item parameters for each subprocess, allowing for example to determine which items specifically foster the use of the extreme or middle categories. A potential disadvantage of IRTrees may be seen in the dichotomization of responses in the definition of pseudo-items pertaining to agreement judgments or other subprocesses, which may reduce the precision of estimating the underlying construct (but see Plieninger and Meiser, 2014). Recent development of IRTrees, however, allow for ordinal pseudo-items and for assessing the same construct over several binary pseudo-items (e.g. Meiser et al., 2019), which remedies the potential disadvantage as demonstrated in our empirical application with a multidimensional node parameterization.

A particular challenge of IRTrees compared to multidimensional PCMs concerns the modeling of response styles that go along with the target trait, such as ARS. Modeling ARS has been implemented in IRTrees with the aid of a Bayesian hierarchical estimation approach to multinomial processing trees (Pleninger and Heck, 2018), but it has not yet been implemented in a version that is easily accessible to applied researchers. Lastly, we would like to caution against a strict interpretation of the order of processes in IRTrees, which may be suggested by tree diagrams: The order of processes in an IRTree diagram does not imply a temporal sequence, but it entails logical dependencies as reflected in the conditional definition of pseudo-items. Besides other caveats and potential pitfalls, Pleninger (2020a) provides an extensive discussion of when and why the order of processes should not be interpreted and which logical dependencies may be important.

While in this chapter, we have used one-parameter variants of PCMs and IRTrees with discrimination parameters fixed to 1 or constrained to be equal across rating items, the response style models can be extended to two-parameter variants with discrimination parameters varying over rating items. For the dimensions reflecting the construct of interest, the discrimination parameters can be interpreted as the strength of the influence of the construct on the item response. Analogously, discrimination parameters of response style dimensions reflect the extent to which single items are impacted by response style dimensions. Therefore, item-specific discrimination parameters of response style dimensions might be helpful to identify items that are influenced by response styles to a larger or smaller extent (see e.g., Henninger and Meiser, 2020b, for an application, discussion, and explanatory model).

Response style models can also be extended to account for different strengths or types of response styles across groups or subpopulations, such as in cross-cultural research (see e.g., Bolt et al., 2014; Henninger, 2020; Morren et al., 2012; Plieninger, 2020a, for examples) or mixture distribution analyses (Kim and Bolt, 2021; Tijmstra et al., 2018). Those extensions of response style models, allow us to compare latent means and variances, not only of the constructs to be measured, but also of response style dimensions. In consequence, they might provide interesting insights into how response processes differ between countries, socio-demographic groups or latent subpopulations of respondents.

In our empirical example, we used the free, open-source programming environment R (R Core Team, 2020) together with the package *mirt* (Chalmers, 2012, OSF⁴ repository for example R code), but there are multiple software alternatives that can be used for estimating response style models. For instance, the R package *TAM* (Kiefer et al., 2017) provides flexible options to specify diverse psychometric models using design matrices (see Henninger, 2020; Henninger and Meiser, 2020b, for example code). To fit IRTree models to polytomous data, the R packages *IRTrees* (De Boeck and Partchev, 2012) or *ItemResponseTrees* (Plieninger, 2020b) provide user-friendly functions that facilitate the creation of pseudo-items. Alternatively, the commercial software program *Mplus* (Muthén and Muthén, 2012) can be used to specify multidimensional extensions of ordinal IRT models as well as IRTree approaches (for examples of *Mplus* syntax, see Böckenholt and Meiser, 2017; Meiser et al., 2019). As an alternative, multidimensional IRT and IRTree models can be estimated in a Bayesian estimation framework, as discussed, for example, by Leventhal and Stone (2018), Bolt et al. (2014) or Plieninger and Heck (2018). Independent of the choice of software, modeling response styles across different constructs, or using additional heterogeneous items or anchoring vignettes (Bolt et al., 2014), facilitates estimation of these complex psychometric models and enhances the interpretation of latent factors.

Aside from using statistical models to control for response styles in the measurement of latent propensities, recent developments in psychometrics have considered alternative response formats as means to reduce biasing effects, such as response formats that distinguish categorical agreement judgments from ratings of response intensity (Böckenholt, 2017) or rankings of items pertaining to different latent constructs (so-called multidimensional forced-choice format; Wetzel and Frick, 2020). The combination of statistical modeling in data analysis and innovative response formats in test construction allows researchers to enhance the validity of educational measurement and to better specify and test theoretical assumptions on latent response processes.

Introduction to psychometric simulation

Psychometric research questions may be answered by theoretical derivations, empirical data collection, or simulation-based methods. Theoretical studies typically derive new methods or evaluate current methods mathematically. Empirical studies require the collection of data or analysis of secondary data. Although in a majority of studies using psychometric methods data is collected through the use of achievement tests or attitudinal measures to help answer important questions, these empirical studies are unable to answer all questions of interest to psychometric researchers. For example, questions in a parameter recovery study investigating the accuracy of estimating an item discrimination parameter using a new estimation routine, or questions in a comparative study that focus on Type I error rates of a model-fit statistic are not answerable with empirical methods. This is because in empirical studies, the researcher does not know “truth”, such as the true population parameter values, or whether the mechanism giving rise to the data is the same as the model being fit to the data, each of which are necessary for answering these types of methodological research questions. As an alternative to empirical approaches, simulation studies address a unique class of research questions that require knowing the truth, such as those that focus on parameter recovery or a comparison of methods. In answering these questions, Monte Carlo simulation studies, often simply called “simulation studies”, use data generated by the researcher in a carefully planned experiment.

Simulation studies are prevalent in recent psychometric literature. In five major educational and psychological measurement journals from the years 2015 through 2019, at least one-quarter of published articles utilized simulation methods, as shown in **Table 1**. Furthermore, of the five journals reviewed, the majority of articles were simulation based in four, with *Applied Psychological Measurement* publishing the largest percentage of simulation studies (86.24%), followed by *Journal of Educational and Behavioral Statistics* (74.29%), *Journal of Educational Measurement* (55.56%), and *Educational and Psychological Measurement* (51.97%). These simulation entries come from a wide variety of research areas, such as structural equation modeling, hierarchical linear modeling/multilevel modeling, differential item functioning, computer adaptive testing, cognitive diagnostic models, response styles, with item response theory being the most common across all. It is also quite common for publications to include studies that contained both empirical and simulation components, such as those in the *Journal of Educational and Behavior Statistics* where a majority of published studies contained both simulation and empirical parts.

One reason for the popularity and prevalence of Monte Carlo simulations is that a simulation study facilitates answering questions not possible using empirical methods as data is generated under the control of the psychometric researcher. Specification of data generation models under a variety of conditions allows the researcher to understand psychometric model behavior in varying circumstances, helping provide context for situations where the model is applied empirically. For example, survey responses may be generated using a structural equation model with varying conditions of sample size or patterns in factor loadings. Specifying the levels of these conditions is critical as the generalizability of the results are a direct consequence of the conditions selected. Simulation researchers attest to the need to balance the number of factors in a study, the levels of each of those factors, and the generalizability of the results.

In addition to studies answering simulation-based research questions, multiple publications provide guidance to psychometric researchers performing simulation studies (e.g., [Harwell et al., 1996](#); [Lee, 2015](#); [Feinberg and Rubright, 2016](#)). Other publications are tutorial-focused, providing application based guidance to performing simulation (e.g., [Ames et al., 2020](#); [Beaujean, 2018](#);

Journal of Educational Measurement	135	26	30

Leventhal and Ames, 2020) as well as details to performing simulation studies for different classes of models (e.g., Luecht and Ackerman, 2018). As with empirical studies, most simulation studies have the same key components, even though specifics will vary among studies. Harwell et al.'s (1996) eight steps for simulation studies provide a viable framework for simulation studies in psychometrics. This eight-step framework includes: (1) specifying the research question(s), (2) defining and justifying conditions, (3) choosing an experimental design, (4) generating data, (5) estimating parameters, (6) comparing true and estimated parameters, (7) replicating the procedure a specified number of times, and (8) analyzing results.

Step 1: Specifying the research Question(s)

Questions that can be answered using simulation techniques are classified as one of three types: (1) parameter recovery studies, (2) comparative studies, and (3) tool-based where the simulation techniques are used to enhance empirical-based methods. Parameter recovery studies typically focus on the robustness of statistical procedures, estimators, or test statistics. Common outcomes of parameter recovery studies are parameter estimate bias, efficiency, and consistency. Comparative studies are used to evaluate error rates (e.g., Type I, Type II), statistical power, and model comparison procedures. Even though the term “simulation studies” is commonly used for either parameter recovery or comparative studies, simulation techniques are useful in other areas of psychometric research. For example, simulation techniques assist in generating empirical sampling distributions under a null hypothesis in a frequentist framework, posterior predictive model checking in a Bayesian framework, qualities of interest reporting, model cross validation studies, and resampling methods such as bootstrapping, jackknifing, and permutation tests. Additionally, simulation techniques can be particularly helpful in answering research questions that would alternatively stretch ethical boundaries when using human subjects. For example, researchers may want to investigate the impact of a technology disruption on a computer adaptive test in a high-stakes setting. Because it would be unethical to disrupt an exam session in real life, researchers may turn to simulation techniques to gauge the impact of the disruption on ability estimation.

Step 2: Defining and justifying conditions

Simulation studies require delicately balancing the comprehensive nature of the design, feasibility of the study, and generalizability of the results. To help, the factors selected should meaningfully impact practice, necessitating an examination of their appropriateness in each study on a case-by-case basis. Factors of the simulation are analogous to independent variables of an experiment: they are manipulated by the researcher in order to examine their effect on the outcome (i.e., dependent variable). For example, the model selected to generate and analyze the data, typically dictated by the research questions, must be worthwhile of study with broad enough application for interest beyond the scope of simulation. Results from the simulation study apply only to the specific models used and parameter values selected to generate data. Therefore, in addition to justifying the model, parameter values used for generation (i.e. true parameter values) must be grounded in literature or practice.

In order to generate data, model parameters are considered known, or “true”. Three ways of selecting these true generating parameters exist. First, generating parameters may be fixed at specified values within a range. For example, item difficulties in an IRT framework are set to equally spaced values between -2 and 2 . Second, model parameters may be randomly selected from a range of values such as item difficulties being randomly drawn from a uniform distribution of values between -2 and 2 . Third, generating parameter are based on empirical results such as item difficulties fixed to empirical estimates from a prior or paired study. In most simulations, it is common that multiple methods are employed. Continuing the IRT example, item difficulties may be randomly drawn from a range of empirical estimates. Whichever technique is used to select these true parameters, the method used with a sound justification grounded in literature or a paired study must be explicit in the manuscript. This ensures reproducibility and helps contextualize the generalizability of the results. In the case where multiple models are used to generate and analyze data, careful consideration must be made to the selection of model parameter values to assure comparability. In these examples, the generating model or analysis model become independent variables of the study.

Step 3: Specifying the experimental design and outcomes of interest

Simulation studies commonly use factorial designs, where independent variables, known as simulation factors; dependent variables, known as outcomes of interest; and simulation constants, known as fixed factors, are specified and justified. A combination of levels from all factors is called a simulation condition. Simulation studies are defined by the size of the factorial designs or the number of simulation conditions. For example, a $3 \times 2 \times 5$ simulation study has three independent variables with 3, 2, and 5 levels, respectively, resulting in 30 simulation conditions. Interpretability of the factorial design must be balanced with generalizability of the results. Partly due to this balance, in Monte Carlo simulations it is equally important to specify and justify fixed factors. Fixed factors limit the generalizability of the results so their use must add to usefulness of the study in some other way. To justify fixed conditions, previous research and theory can be beneficial. For example, if investigating the effects of estimating item difficulties, it may be worth fixing test length to make the study feasible, but include sample size as a simulation factor with multiple levels to improve generalizability. Or, if a specific empirical scenario is of interest to the researcher, conditions from the empirical study can be used as fixed conditions in the simulation.

Factor selection is critical, and is influenced by previous literature in the domain, research questions of the study, a paired empirical study, or application interests. For example, SEM studies may focus on manipulating estimation methods, number of latent factors, or factor loading patterns while IRT studies may focus on varying the number of items, sample size, or true ability distributions. In classical test theory simulations, many of these same factors might be considered important by researchers (e.g., sample size), but other factors like variability of the observed score distribution may also be manipulated. Once factors are selected, each level must be meaningful and justified. As an illustration, unless a specific case can be made, there likely is no practical difference between a test with 10 items and a test with 12 items. There may, however, be a meaningful difference between a test with 10 items and one with 20 items. More general interpretations, such as the effects on the outcome when test length is doubled, can be drawn if the factor levels are sufficiently distinct.

Factor level selections typically relate to properties and assumptions of estimators. If trying to estimate latent ability in IRT, for example, test length should be included as a factor rather than sample size, but sample size must be fixed to be large enough to assure no confounding effects of low sample size. Some experts consider including levels where good results are to be expected such as a large number of items when estimating latent ability. This can serve as a baseline condition although inclusion needs to be balanced with practicality of the study.

Simulation factors also depend on the estimation framework. The two primary estimation frameworks used in psychometrics are Bayesian Markov chain Monte Carlo (MCMC) and frequentist Maximum Likelihood estimation (MLE). Even though both methods require specification of the analytic and generating models, which may differ from each other, with the stochastic model often referred to as the likelihood, Bayesian MCMC methods differ from MLE in many ways.

One primary difference is in the use of prior distributions, which are hypotheses about the shape of the distribution of parameter values. For each parameter, the prior distribution and the likelihood combine to form the posterior distribution. In simplified terms, the MCMC process updates the prior distribution and yields a new probability distribution, reflecting plausible values of the parameter. When the prior is combined with the likelihood, each value in the likelihood is weighted by its prior probability. With little to no prior information contained in the prior distribution, each value in the likelihood is equally weighted, and the posterior distribution is nearly identical to the likelihood function. However, with more prior information (i.e., the researcher uses informative priors), values in the likelihood receive more weight where the prior has more density and less weight where the prior has a lower density. The result is a posterior that is shrunk toward the prior. Further, as sample size increases, the prior becomes less and less influential. Because many Monte Carlo simulation studies vary sample size as a condition, priors may be influential in some levels of the condition, but not influential in others. Because of this interaction, the choice of prior may be included as an additional factor (e.g., [Natesan et al., 2016](#)) when sample size is manipulated.

Regardless of estimation framework, the outcomes of interest are dictated by the type of simulation study. For parameter recovery studies, these dependent variables commonly reflect parameter estimates, empirical error rates, or sampling distributions of parameter estimates. Alternatively, comparative studies examine test statistics and model-fit statistics to calculate error rates or statistical power. For other studies that use simulation techniques, outcomes of interest widely vary. In one example, the study of an estimation algorithm may focus on the number of iterations it takes the method to converge under varying factors or the resulting number of improper solutions (e.g., negative variance estimates in structural equation modeling). Specific details of calculating these outcomes does depend on the estimation framework used as highlighted in steps 5 and 6.

Step 4: Simulating data under the specified conditions

Methods and software used to generate data should be adequately described in a manuscript to allow replication of the study. If programs are developed, or common routines are modified, they must be verified for accuracy. All properties of generated data must be validated to confirm simulation conditions, both manipulated and fixed, are accurately reflected in the data. This is known as data generation validation and is analogous to mitigating and documenting validity concerns during data collection in an empirical study. Validation may be performed by using previously well-documented estimation routines or through graphical means. For example, in IRT, a researcher may simulate a large number of individuals (whether or not it is a condition), estimate item parameters with a known estimation algorithm or software package (e.g., marginal maximum likelihood in FlexMIRT), and compare the true and

estimated item parameters to make sure the data generation process is accurate. Alternatively, validation can be performed graphically. In some cases, a simple histogram can be used, such as visually confirming that a latent trait follows a normal or skewed distribution as intended. Data validation is not commonly reported in full detail, but all key aspects of the data generation must be validated just as any data collection procedure would be validated in an empirical study.

Step 5: Estimating parameters

After the data is generated and validated, the next step is to fit the analysis model(s) to the data. There may be a single analysis model if performing a parameter recovery study or multiple analysis models if performing comparative studies. Fit of analysis models in parameter recovery studies results in estimated parameters of interest, whereas estimation of models in comparative studies result in, for example, the calculation of model-fit statistics. Each simulation should document the exact estimation methods, providing details of the estimation algorithm and software choice. Simulation studies using either MCMC methods or MLE must assess convergence. MCMC methods may rely on visual tools, such as trace plots, or statistical measures, such as Geweke (1992) and the Gelman-Rubin diagnostic (Gelman and Rubin, 1992). MLE algorithms may use tolerance. Both methods should specify the number of iterations necessary to achieve convergence, which helps the simulation audience understand the applicability and generalizability of the results.

MCMC estimation considerations

While there are few guidelines for Bayesian simulation studies, several authors have provided reporting guidelines on the details of MCMC (e.g., van Doorn et al., 2019; Sung et al., 2005). Many of these same guidelines apply to reporting Bayesian simulation studies and they reflect the decisions that must be made by the researcher in setting up and conducting the Monte Carlo simulation. For example, Sung et al. (2005) suggest reporting the exact prior distribution specifications, as well as providing a justification for the choice of priors. In terms of computational issues, authors should report the specific software choice, MCMC sampling algorithm, and a range of other technical details (Sung et al., 2005). Specific MCMC algorithm examples include: Metropolis Hastings (Metropolis et al., 1953; Hastings, 1970), implemented in the SAS MCMC procedure (SAS Institute Inc., 2015); Gibbs (Geman and Geman, 1984), implemented in Mplus (Muthén and Muthén, 1998–2017); and Hamiltonian Monte Carlo (Duane et al., 1987), implemented in Stan (Stan Development Team, 2017). Because Bayesian estimation results in a full parameter posterior distribution, many researchers choose to summarize the posterior using a point estimate, such as the posterior mode (i.e., Maximum a Posteriori, MAP) or mean (i.e., Expected a Posteriori, EAP). The posterior is a probability distribution; as such, a single value may not be adequate to reflect the estimated parameter and an indicator of posterior precision is critical.

Maximum likelihood estimation considerations

MLE-specific algorithms used in psychometrics include Marginal MLE (Bock and Aitkin, 1981) and joint MLE (Andersen, 1972; Fischer, 1981; Haberman, 1977). Despite the differences in algorithms and underlying philosophies between Bayesian and MLE methods, for many of the important details in Bayesian MCMC estimation, there is a MLE equivalent. For example, the precision of the point estimate in MCMC estimation is summarized using quantities such as posterior highest density interval or the posterior standard deviation. In MLE, the parameter standard error is used to summarize the precision of the parameter.

Step 6: Comparing true and estimated parameters

Comparison depends on the type of simulation study and specific research questions. Feinberg and Rubright (2016) state, “It is also important to consider how simulations were evaluated in previous research, such that similar dependent variables can be applied to facilitate comparisons and allow results from your simulation to build upon previous research” (p. 40). If the study is a parameter recovery study, the research question is asking if the estimation routine is accurate across multiple levels of each condition. In frequentist studies relying on MLE, the parameter point estimate is compared to the generating value. These types of simulations use metrics like bias, standard error, root mean square error (RMSE), and absolute bias to determine accuracy and precision. The deviation between the estimated parameter and true generating parameter is the fundamental unit for many parameter recovery studies. Frequentist studies may also look at interval estimation, such as the number of confidence intervals that capture the generating value. When using MCMC methods, researchers commonly use a point estimate like the EAP or MAP for this comparison to compute the deviation. Coverage, a measure of whether a specified posterior interval encompasses the generating value, may be used in an effort to avoid discarding information present in the full posterior that is missed by the using of only a point estimate.

If the purpose of the simulation is to evaluate a new procedure or to compare models, additional measures need to be computed beyond the parameter point estimates. For example, McKinley and Mills (1985) evaluated four goodness-of-fit procedures for item response models on their ability to discriminate cases of fit from cases of misfit. The comparison in this type of study involves three conditions: (1) the erroneous conclusion that the analysis model does not fit the data when, in fact, the data were generated with that model; (2) the erroneous conclusion of fit when the analysis model is not a restricted form of the generating model; and (3) the

correct conclusion that the analysis model does not fit the data when the data were generated with a more complex version. Simulation studies often calculate the prevalence of each condition. Because MCMC studies do not rely upon null hypothesis statistical testing procedures, equivalent quantities might be “hit rates” for correct conclusions and “false positives” for incorrect conclusions.

Step 7: Replicating the procedure a specified number of times

Replicating within conditions allows for more generalizable simulation results through introduction of variability in generating parameter values and their estimates. [Feinberg and Rubright \(2016\)](#) provide recommendations on the number of replications for a simulation study in IRT, pointing out that “More replications are always better in terms of producing a more accurate and reliable estimate of the parameters of interest” (p. 39). However, more replications require more computational time which will often constrain the number of replications and there becomes a point in which diminishing returns are reached. [Bandalos \(2006\)](#) suggested that 500 replications were large enough for structural equation modeling simulations in the frequentist framework, arguing this number of replications would provide stable standard error estimates. In IRT, some researchers have used as few as 30 replications (e.g., [Wang et al., 2018](#)), but other have used 1000 or more (e.g., [Miyazaki et al., 2019](#)). There are few guidelines on the number of replications for Bayesian simulation studies, but a smaller number of replications tend to be used in comparison to frequentist simulations, as Bayesian methods tend to be more computationally time consuming. For a multidimensional item response application, [Leventhal \(2019\)](#) used 25 replications per condition where within-replication posterior distributions were built using 20,000 sampled values of the MCMC chain.

Determining the number of replications requires balancing feasibility of the study and generalizability of the results. Methods to increase the efficiency of the simulation can alleviate simulation resource cost, such as the time to perform the study, allowing more conditions. For example, if stability of results across replications is likely, the number of replications can be reduced, however if stability is unlikely, the number of replications should be increased limiting the number of feasible simulation conditions. Noise or variability can be reduced by randomly sampling from the same generated dataset across multiple conditions increasing the efficiency of the design. Finally, it is important to understand that different outcomes require a different number of replications. Parameter recovery studies focused on bias generally require fewer replications than parameter recovery studies investigating the standard error of parameter estimates. Prior studies or theoretical literature can be used to determine and justify the number of replications necessary for simulation conditions.

Step 8: Analyzing results based on the design and research question

The crossing of conditions, combined with a large number of replications, and the potential for multiple outcomes produces abundant data and output. As such, the logical, coherent summarization and presentation of results is critical to drawing conclusions from the simulation. The interpretable presentation of results typically takes on one or more of the following forms: (1) graphical displays, (2) tabular summarization by condition, and (3) statistical analysis. The statistical analysis appropriate when conditions have discrete levels, for example, is an ANOVA.

The outcome measures of the analysis, like bias or Type I error, are summarized across all replications within a single condition. For example, bias for parameter θ in condition levels i, j , and k is the average deviation between the true and generating value:

$$Bias_{i,j,k} = \sum_R \frac{(\hat{\theta}_{i,j,k,R} - \theta_{True,i,j,k})}{R} \quad (1)$$

where R is the number of replications, $\hat{\theta}_{i,j,k,R}$ is the estimated parameter value and $\theta_{True,i,j,k}$ is the generating parameter value, which is commonly fixed across all replications for studies of frequentist methods. The researchers could determine, using ANOVA, which conditions have a significant effect on the outcome. Analysis of variance techniques facilitate succinctly analyzing each factor and their interactions. Factors are commonly treated as fixed effects and may be considered a within- or between-subjects independent variable. All interactions among factors crossed in the simulation design are analyzed. Effect sizes, such as partial eta-squared (η_p^2), which is a measure of variance accounted for, are used to determine meaningful interactions rather than statistical significance due to the influence of the large replication numbers. Interactions and main effects determined to be of significant interest are interpreted further through follow-up analysis and graphical displays.

Another approach is for values of the outcome to be compared to some heuristic of an acceptable level of the outcome and illustrated graphically. For example, a Type I error rate is often set at 0.05. Any condition combinations for which the Type I error exceeds 0.05 could then be used to guide practitioners in their applied research. There is no single best analysis approach, as the analysis and display of results depend upon the research question and research audience.

Example

To illustrate the concepts, we provide a complete example of a simulation study in the IRT framework. Consider an example scenario in which a researcher is investigating the Type I error rates of a hypothesis test for model-data fit for a two-parameter logistic

model using a chi-square statistic (Step 1). They vary latent trait distribution (positive skew, negative skew, normal) using small, moderate, and large sample sizes (Step 2). They generate responses to a 20-item test (test length is a fixed factor) using item difficulties randomly selected from a standard normal distribution and item discrimination parameters from a log-normal distribution. To evaluate their research questions, sample size levels are crossed with trait distributions resulting in a 3×3 or 9 condition simulation design. For each replication, the outcome considered is the chi-square fit statistic (Step 3). The generating model simulates data under the null hypothesis of model data fit in each condition. Latent trait distributions are validated using a histogram of generated latent abilities and item difficulties are confirmed via visual inspection of generated item characteristics curves (Step 4). Using marginal maximum likelihood, the analysis model is fit to the data (Step 5) and the hypothesis test is conducted calculating the chi-square statistic. Because Type I error is the research focus, the analysis model and generating model are the same. The researcher specifically records whether the null hypothesis of model-data fit is rejected within each replication (Step 6). Steps 4, 5, and 6 are replicated 1000 times (Step 7). After replication, Type I error rate is calculated as the proportion of times the null hypothesis is rejected out of 1000 replications (Step 8). Using a tabular display, the effects on Type I error rates of sample size, latent trait distribution, and their interaction are investigated for the Chi-Square test statistic.

Conclusion

Simulation studies are a subset of psychometric studies used to answer questions where knowing true parameters or true model fit is necessary. An understanding of simulations is critical for both consumers and producers of psychometric research. The eight steps outlined provide a framework to most applications of simulation techniques whether it is for parameter recovery studies or comparison studies. As with empirical studies, simulation studies need to be evaluated on a case-by-case basis but have many common elements. Justification of each decision, validation of all syntax, and sufficient detail must be described in order to assure the reproducibility of the study. Simulation studies can quickly become far too complex to be feasible or interpretable, so these concerns must be balanced with the generalizability of the results.
